Epidemiological studies indicate that insulin resistance (IR), a hallmark of type 2 diabetes, is associated with an increased risk of major depression. Here, we demonstrated that male mice fed a high-fat diet (HFD) exhibited peripheral metabolic impairments reminiscent of IR accompanied by elevated circulating levels of branched-chain amino acids (BCAAs), whereas both parameters were normalized by chronic treatment with metformin (Met). Given the role of BCAAs in the regulation of tryptophan influx into the brain, we then explored the activity of the serotonin (5-HT) system. Our results indicated that HFD-fed mice displayed impairment in the electrical activity of dorsal raphe 5-HT neurons, attenuated hippocampal extracellular 5-HT concentrations and anxiety, one of the most visible and early symptoms of depression. On the contrary, Met stimulated 5-HT neurons excitability and 5-HT neurotransmission while hindering HFD-induced anxiety. Met also promoted antidepressant-like activities as observed with fluoxetine. In light of these data, we designed a modified HFD in which BCAA dietary supply was reduced by half. Deficiency in BCAAs failed to reverse HFD-induced metabolic impairments while producing antidepressant-like activity and enhancing the behavioral response to fluoxetine. Our results suggest that Met may act by decreasing circulating BCAAs levels to favor serotonergic neurotransmission in the hippocampus and promote antidepressant-like effects in mice fed an HFD. These findings also lead us to envision that a diet poor in BCAAs, provided either alone or as add-on therapy to conventional antidepressant drugs, could help to relieve depressive symptoms in patients with metabolic comorbidities.

Key words: branched-chain amino acids; depression; hippocampus; insulin resistance; metformin; serotonin

Significance Statement

Insulin resistance in humans is associated with increased risk of anxiodepressive disorders. Such a relationship has been also found in rodents fed a high-fat diet (HFD). To determine whether insulin-sensitizing strategies induce anxiolytic- and/or antidepressant-like activities and to investigate the underlying mechanisms, we tested the effects of metformin, an oral antidiabetic drug, in mice fed an HFD. Metformin reduced levels of circulating branched-chain amino acids, which regulate tryptophan uptake within the brain. Moreover, metformin increased hippocampal serotonergic neurotransmission while promoting anxiolytic- and antidepressant-like effects. Moreover, a diet poor in these amino acids produced similar beneficial behavioral property. Collectively, these results suggest that metformin could be used as add-on therapy to a conventional antidepressant for the comorbidity between metabolic and mental disorders.

Introduction

Insulin resistance (IR), defined as declined sensitivity of tissues to the action of insulin, is associated with the development of serious health concerns such as overweight, hypertension, hyperlipidemia, cardiovascular disease, and type 2 diabetes (T2D). Evidence also suggests the existence of a positive correlation between IR and major depression (Rasgon and Kenna, 2005). Indeed, the induction of IR in rats or mice, using prolonged exposure to high-fat diet (HFD), causes some hallmark symptoms of depression including anxiety, anhedonia, and despair (Miyata et al., 2004; Ho et al., 2012; André et al., 2014; Gupta et al., 2014; Dutheil et al., 2016; Yang et al., 2016; Zemdegs et al., 2016; Hassan et al., 2018) and exacerbates behavioral abnormalities observed in animal models of depression (Abildgaard et al., 2011; Liu et al., 2014).

Although the neurobiological mechanisms underlying the relationship between IR and depression have yet to be identified, impairments of brain plasticity have been incriminated. In humans, associations between the severity of IR and the reduction of brain volume have been unveiled (Last et al., 2007; Phillips et al., 2018). In keeping with these results, mice or rats developing IR display deficits in adult hippocampal neurogenesis (Lindqvist et al., 2006; Stranahan et al., 2008; Lang et al., 2009; Park et al., 2010) in a manner similar to that observed in animal models of depression (Surget et al., 2008; David et al., 2009). In marked contrast, insulin-sensitizing strategies exert neuroprotective/neurotrophic effects in rodents (Zhong et al., 2018). This has been reported with the antidiabetic agents liraglutide, glyburide, and metformin (Wang et al., 2012; Su et al., 2017; Weina et al., 2018). Given the beneficial role of the serotonin (5-HT) system in the enhancement of brain plasticity (Quesseveur et al., 2013), the possibility that deficits in 5-HT neurotransmission underlie the comorbidity between T2D/IR and depression, has been raised. Consistent with this hypothesis, decreased levels of tryptophan were detected in the CNS of patients with T2D (Kloiber et al., 2010; Herrera-Marquez et al., 2011) or in rodents fed an HFD (Kim et al., 2013; Derkach et al., 2015). Using intracerebral microdialysis, we showed that mice fed an HFD displayed lower basal hippocampal extracellular 5-HT concentrations (Zemdegs et al., 2016). Exaggerated stimulation of the monoamine oxidase activity—the enzyme responsible for 5-HT degradation—or the indoleamine 2,3-dioxygenase—the enzyme that metabolizes tryptophan along the kynurenine pathway—are putative explanations for such neurochemical changes (André et al., 2014; Diné et al., 2014; Gupta et al., 2014). We recently proposed that an increased sensitivity of inhibitory somatodendritic 5-HT_{1A} autoreceptors in the dorsal raphe (DR) could be an alternative mechanism by

Table 1. Composition of the standard and high-fat diets

Diet composition	STD	HFD	HFD-BCAA ^{+/+}	HFD-BCAA ^{+/-}
Proteins (kcal%)	26	20	20	19
Carbohydrates (kcal%)	60	35	34	35
Lipids (kcal%)	3	45	46	46
Amino acids (g/kg)				
BCAAs				
Leucine	18.7	18.7	18.7	9.35
Isoleucine	11.7	11.7	11.7	5.85
Valine	14	14	14	7
Tryptophan	1.9	2.1	2.3	2.3
Energy content (kcal/kg dry diet)	2790	4720	4570	4590

which IR might hinder hippocampal serotonergic transmission (Zemdegs et al., 2016). Despite these possibilities, the role of branched-chain amino acids [BCAAs; leucine (Leu), isoleucine (Ile), and valine (Val)] in the relationship between IR and brain extracellular 5-HT concentrations is gaining interest. Indeed, elevated circulating BCAA levels predict the severity of IR (Newgard et al., 2009; Gannon et al., 2018) while limiting the uptake of tryptophan into the brain through the blood–brain barrier (BBB) by the large neutral amino acid transporter 1 (LAT1; Pardridge, 1998). Thus, the rate of 5-HT production may be affected by BCAAs, thereby leading to anxiodepressive symptoms, as shown in clinical (Fellendorf et al., 2018) and preclinical studies (Coppola et al., 2013; Scaini et al., 2014; Asor et al., 2015).

On this backdrop, the present study determined whether metformin (an insulin-sensitizing drug belonging to the class of biguanides) exerts beneficial effects on glucose metabolism, on the electrical activity of DR 5-HT neurons, on the 5-HT release at the nerve terminals, and on emotional behavior in a mouse model of comorbid T2D/IR and depression. Moreover, given the association among BCAAs, IR, and depression, and in light of their negative impact on 5-HT neurotransmission, we also tested the possibility that the antidepressant-like effects of metformin rely on an attenuation of circulating BCAA levels.

Materials and Methods

Animals, diets, and drugs. The 5- to 7-week-old C57BL/6J male mice (Elevages Janvier Farms) were housed four to five mice per cage under standard conditions with a 12 h light/dark cycle. After 1 week of acclimatization, mice were randomly assigned to receive free access to a standard diet (STD; STD A04, SAFE), an HFD (D12451, Research Diets) or a half-BCAA-HFD (HFD-BCAA^{+/-}; MD.1610 version, ENVIGO) up to 16 weeks (Table 1). We ensured that tryptophan quantity, the precursor for 5-HT synthesis, was equivalent between STDs and HFDs. In a specific experiment, STD and HFD mice were chronically administered with the insulin-sensitizing agent metformin at the active dose of 300 mg/kg/d (Sigma-Aldrich) or the selective serotonin reuptake inhibitor (SSRI) fluoxetine (Flx) at a dose of 18 mg/kg/d (Biotrend Chimikalien). Both drugs were dissolved and given in the drinking water. The water consumption per mouse per day (24 h) was monitored during the course of treatments. Because daily water consumption might have differed between STD and HFD mice, metformin and fluoxetine concentrations in drinking water were adjusted accordingly to achieve comparable dosing. The purpose of giving the metformin and fluoxetine in drinking water was to maintain a constant level of these pharmacological compounds. For example, metformin is typically given to patients in an extended-release form so that its effects can be sustained over long durations. All experimental procedures were conducted in accordance with the European directive 2010/63/UE and were approved by the French Ministry of Research and local ethic committees (C2EA Grand Campus de Dijon N°105, APAFIS #12342-2017082111489451 v6, and CE2A Université de Bordeaux N°50, APafis #8928).

Figure 1. Chronic administration of metformin reverses HFD-induced glucose metabolism impairment. Two groups of mice were fed an HFD for 16 weeks and chronically treated with Met (300 mg/kg) or its Veh in the drinking water for the last 4 weeks. The control group of mice was fed an STD and administered the Veh. **A–H**, Data are the mean \pm SEM of body weight from week 0 to week 16 (**A**), final body weight ($F_{(2,27)} = 10.4$; $p = 0.0004$; **B**), fluid intake (**C**), basal fasting glycemia ($F_{(2,27)} = 23.9$; $p = 0.0001$; **D**), basal fasting insulinemia ($F_{(2,27)} = 10.1$; $p = 0.0008$; **E**), HOMA-IR ($F_{(2,27)} = 11.2$; $p = 0.0005$; **F**), and glucose tolerance in response to the intraperitoneal administration of glucose (for AUC_{0-120} : $F_{(2,27)} = 24.9$; $p = 0.0001$; 2 g/kg; **G**, **H**). $n = 10$ mice/group. * $p < 0.05$ and *** $p < 0.001$: significantly different from the STD-Veh group. # $p < 0.05$ and ### $p < 0.001$: significantly different from the HFD-Veh group.

Metabolic parameters: glucose tolerance test. Animals were individually housed, weighed, and fasted for 5 h with free access to water. Blood glucose level was measured from tail prick (Accu-Chek Performa Glucometer, Roche) at 0 min (basal), 15, 30, 45, 60, 90, and 120 min after the administration of glucose (2 g/kg) in an intraperitoneal glucose tolerance test (ipGTT). During ipGTT, the area under the curve (AUC) was calculated using the coordinate axis set at 100. For plasma insulin levels, blood samples were collected through tail prick in heparinized capillary tubes (Microvette CB 300 K2E, Sarstedt). Blood was centrifuged (10,000 rpm; 10 min), and plasma was collected and stored at -80°C before analysis. Insulin was measured using the AlphaLISA method, according to manufacturer instructions (human insulin kit; catalog #AL204C, PerkinElmer). The homeostasis model assessment (HOMA) of IR (HOMA-IR) scores were calculated from glucose and insulin concentrations obtained

from mice after 5 h of fasting. The following equation was used: fasting blood glucose (in milligrams per deciliter) \times fasting insulin (in nanograms per milliliter)/405. HOMA-IR ≥ 2.8 represents an insulin resistance state (Matthews et al., 1985).

Plasma amino acids analysis. The BCAA concentration from plasma samples was measured using a BCAA (leucine, isoleucine, and valine) assay kit (catalog #MAK003, Sigma-Aldrich) according to manufacturer instructions using a coupled enzyme reaction, which results in a colorimetric (450 nm) product, proportional to the BCAA present.

In vivo single-unit recordings of 5-HT neurons in the dorsal raphe nucleus. Mice were anesthetized with chloral hydrate (400 mg/kg, i.p.) and placed in a stereotaxic frame with the skull positioned horizontally. To maintain a full anesthesia, chloral hydrate supplements of 100 mg/kg, i.p., were given as needed. Extracellular recordings in the DR were performed using single glass micropipettes (Stoelting Europe) pulled on a pipette puller (Narishige) and preloaded with a 2 M NaCl solution (impedances from 2.5 to 5 M Ω). Micropipettes were positioned 0.2–0.5 mm posterior to the interaural line on the midline and lowered into the DR, attained at a depth between 2.5 and 3.5 mm from the brain surface. 5-HT neurons were identified using the following criteria: a slow (0.5–2.5 Hz) and regular firing rate and a long-duration positive action potential. In each mouse, several tracts were performed to measure the spontaneous firing rate of DR 5-HT neurons. Firing rates were determined by monitoring the average discharge frequency of DR 5-HT neurons under each experimental condition. The number of neurons recorded per track was also determined.

Brain slice patch-clamp recordings of DR 5-HT neurons. Patch-clamp recordings were performed on brain slices from Pet1-cre-mCherry mice obtained by crossing Pet1-cre mice (a gift from Dr. P. Gaspar, Institut du Fer à Moulin, Inserm, UMR-S 839, Paris, France; Kiyasova et al., 2011) with B6.Cg-Gt(Rosa)26Sor^{tm9(CAG-tdTomato)Hze/J} mice (The Jackson Laboratory). Briefly, 4-month-old mice fed an STD or HFD for 16 weeks were intracardially perfused during the killing of the mice (exagon/lidocaine, 300/30 mg/kg, i.p.) with ice-cold NMDG solution [containing the following (in mM): 1.25 NaH₂PO₄, 2.5 KCl, 7 MgCl₂, 20 HEPES, 0.5 CaCl₂, 28 NaHCO₃, 8 D-glucose, 5 L(+)-ascorbate, 3 Na-pyruvate, 2 thiourea, 93 NMDG, and 93 HCl 37%; pH 7.3–7.4, osmolarity, 305–310 mOsm]. Brains were quickly removed, and 250 μm slices containing the DR were prepared with a vibratome (catalog #VT1000S, Leica) in ice-cold oxygenated NMDG solution before recovery for 12–15 min into at 34°C in the oxygenated NMDG solution. Slices were then transferred at room temperature into an aCSF solution [containing the following (in mM): 124 NaCl, 2.5 KCl, 1.25 NaH₂PO₄, 2 MgCl₂, 2.5 CaCl₂, 2.5 D-glucose, and 25 NaHCO₃; pH 7.3–7.4, osmolarity, 305–310 mOsm] for at least 1 h.

Slices were transferred in the recording chamber placed under a microscope (Nikon) outfitted for fluorescence and IR-differential interference contrast video microscopy and perfused with oxygenated aCSF at 2–3 ml/min in the recording chamber. Viable DR 5-HT neurons were

Figure 2. Chronic administration of metformin reverses HFD-induced increase in plasma BCAA levels. Two groups of mice were fed an HFD for 16 weeks and chronically treated with Met (300 mg/kg) or its Veh in the drinking water for the last 4 weeks. The control group of mice was fed an STD and administered the Veh. Data are the mean \pm SEM of plasma levels of BCAAs (Leu, Val, Iso-Leu; $F_{(2,18)} = 13.7$; $p = 0.0003$). $n = 7$ mice/group. ** $p < 0.01$: significantly different from STD-Veh group. ### $p < 0.001$: significantly different from the HFD-Veh group.

visualized with a fluorescence video camera (Nikon). Borosilicate pipettes (4–6 M Ω ; outer diameter, 1.5 mm; Sutter Instrument) were filled with an intracellular solution [containing the following (in mM): Kgluconate solution: 128 Kgluconate, 20 NaCl, 1 MgCl₂, 1 EGTA, 0.3 CaCl₂, 2 Na₂-ATP, 0.3 Na-GTP, 0.2 cAMP, and 10 HEPES; CsCl solution: 150 CsCl, 2 MgCl₂, 1 EGTA, 3 Na₂-ATP, 0.3 Na-GTP, 0.2 cAMP, and 10 HEPES; pH 7.3–7.4, osmolarity, 280–290 mOsM]. Recordings were made using a Multiclamp 700B amplifier, digitized using the Digidata 1440A interface and acquired at 2 kHz using pClamp 10.5 software (Molecular Devices). Pipettes and cell capacitances were fully compensated, but the junction potential was not corrected. Intrinsic properties of DR 5-HT neurons were recorded in whole-cell clamp mode by injecting a 10 pA current step from –80 to 110 pA on a cell held at –60 mV by constant current injection. sEPSCs or sIPSCs were recording in Vclamp mode on cells held at –60 mV. Picrotoxin (100 μ M) was added to the baths for IPSC recordings. Both sEPSCs and sIPSCs were recorded for 10 min and analyzed during the last minute of the recording.

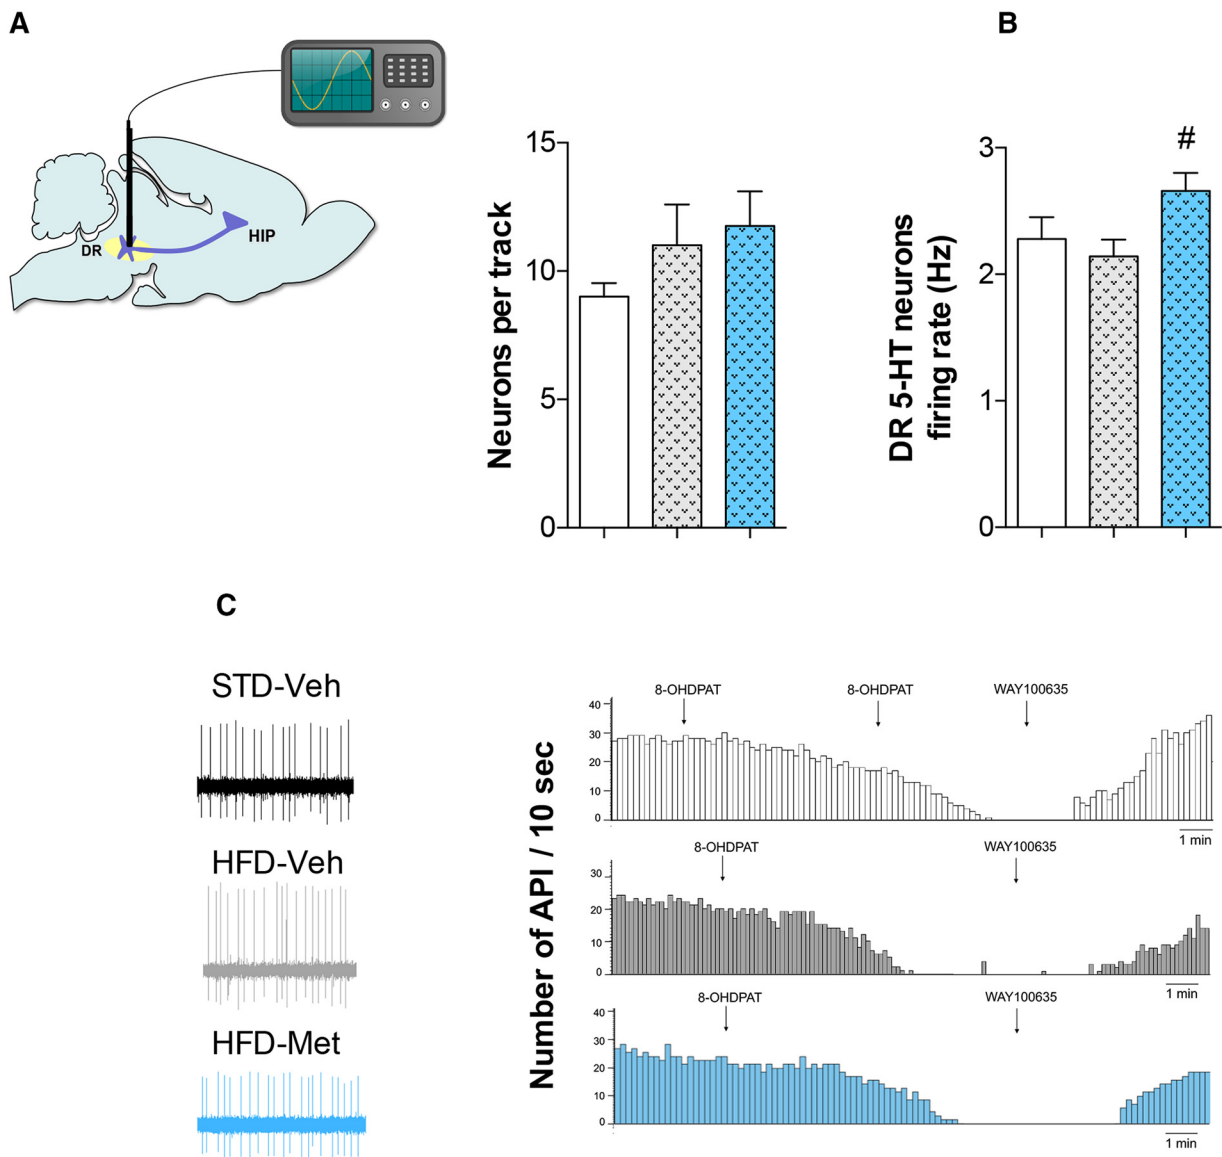

Figure 3. Chronic administration of metformin increases the activity of 5-HT neurons in the DR nucleus of mice fed an HFD. Two groups of mice were fed an HFD for 16 weeks and were chronically treated with Met (300 mg/kg) or its Veh in the drinking water for the last 4 weeks. The control group of mice was fed an STD and administered the Veh. **A, B**, Data are the mean \pm SEM of the number of presumed DR 5-HT neurons recorded per track ($F_{(2,19)} = 1.2$; $p = 0.31$; **A**) and of DR 5-HT firing rate (in Hz; $F_{(2,269)} = 3.5$; $p = 0.031$; **B**). **C**, As a validation of the serotonergic nature of the recorded neurons in the DR, typical traces of a mouse from each experimental group are presented showing their responses to an acute subcutaneous administration of the 5-HT_{1A} receptor agonist 8-OHDPAT (0.1 mg/kg per injection) and the 5-HT_{1A} receptor antagonist WAY100635 (1 mg/kg). $n = 5$ –9 mice/group. # $p < 0.05$: significantly different from the HFD-Veh group.

Figure 4. Comparison between groups was performed using ANOVA ($F_{(2,57)} = 754.1$; $p < 0.0001$). **C–D**, Representative traces of 5-HT neurons from WT (black), HFD (gray), or HFD-Met (blue) mice in response to depolarizing currents (**C**, **D**). Quantification of the number of spikes in response to depolarizing currents from rheobase. Data are the mean \pm SEM of the number of spikes in response to relative current injected (ANOVA: $F_{(16,408)} = 3.795$; $p < 0.0001$). **E**, Representative traces of 5-HT neurons from STD (black), HFD (gray), and HFD-Met (blue) mice in response to phenylephrine (Figure legend continues.)

Intracerebral microdialysis in the ventral hippocampus of awake freely moving mice. Mice were implanted with a home-made microdialysis probe in the ventral hippocampus (vHP). Stereotaxic coordinates from bregma were as follows (in mm): antero-posterior (AP), -2.5 ; lateral (L), ± 2.7 ; and dorso-ventral (DV), -3.0 . Twenty-four hours later, probes were connected to a microinjection pump for a continuous perfusion of aCSF (147 mM NaCl, 2.7 mM KCl, 1 mM MgCl₂, and 1.2 mM CaCl₂, adjusted to pH 7.4 with 2 mM sodium phosphate buffer) containing the serotonin reuptake inhibitor escitalopram (1 μ M) at a flow rate of 1.5 μ l/min. Samples (15 μ l) were collected every 15 min and analyzed with a high-performance liquid chromatography system equipped with a 2.6 μ m C18 reverse-phase analytical column (50 \times 3.0 mm; Accucore, Thermo Fisher Scientific) coupled with electrochemical detection (Dionex Ultimate 3000, Thermo Fisher Scientific). The mobile phase containing 150 mM NaH₂PO₄, 4.76 mM citric acid, 50 mM EDTA, 1.5 mM SDS, 10% methanol, and 15% acetonitrile, adjusted to pH 5.6 with NaOH, was delivered at a flow rate of 0.3 ml/min. The amount of 5-HT in dialysate samples was calculated by measuring the peak heights relative to external standards and was expressed as a percentage of the basal value measured in the four initial fractions. At the end of the experiments, the localization of the microdialysis probes was verified histologically.

Behavioral tests. Animals were tested in different behavioral paradigms starting with the less stressful paradigm and finished with the most stressful one. A 2 d recovery period between each test was respected.

An open field (OF) test was performed in Plexiglas boxes (40 \times 40 cm; Mouse Open Field Arena ENV-510, Med Associates) during a 10 min session. The total ambulatory distance was monitored using the Activity Monitor software (SOF-811, Med Associates) to eliminate any putative bias link to a psychostimulant or a sedative effect.

Elevated plus maze (EPM) was performed in an apparatus manufactured by Ugo Basile, with four 5-cm-wide and 35-cm-long arms, two of which are open: the wall in the closed arms is 15 cm high. Each mouse was allowed to explore the apparatus for 5 min. Global activity was assessed by measuring the time and number of entries into the open arms for which animals display innate aversion.

Novelty suppressed feeding (NSF) was performed in a white plastic box (30 \times 60 cm). Mice were food deprived for 24 h while maintaining water *ad libitum*. On the day of testing, mice were removed from their home cage and transferred to a new clean cage for 1 h. They were then individually placed in the corner of a box with a food pellet on a white square filter paper at the center of the arena under a bright light (\sim 60 W). The latency for the animal to approach and take its first bite of the food was recorded (cutoff, 10 min). Immediately after the test, the feeding drive of each mouse was assessed by returning it individually to the familiar environment of the home cage and measuring the latency to eat and the amount of food consumed over a period of 5 min. Since each mouse was tested with their respective food pellet, the latter parameter was calculated based on caloric value consumed using the following formula [(pellet weight before (in grams) – pellet weight after (in grams)) \times number of calories/gram diet (STD, 2.79 calories/g; HFD, 4.73 calories/

gram)/mouse body weight]. These parameters were determined to ensure the absence of differences in hunger/motivation.

A tail suspension test (TST) was performed using the Tail Suspension Test System (BIOSEB) during a 6 min session. Immobility time was scored as an index of resignation. Mice movements in terms of energy and power in motion were measured to ensure the absence of any locomotor bias.

A splash test (ST) was performed for a 5 min period as previously described (David et al., 2009). After squirting 200 μ l of a 10% sucrose solution on the snout of the mouse, grooming time was scored by a single experimenter as an index of self-care.

Statistical analysis. Unpaired Student's *t* test was used to evaluate the metabolic and behavioral effects of metformin compared with vehicle (Veh) in mice fed an STD. For all other experiments, mice were fed an STD or HFD, and one- or two-way ANOVAs were applied, when appropriate, by *post hoc* tests (protected least significant difference) using GraphPad Prism (GraphPad Software). In the NSF, we used the Kaplan–Meier survival representation to indicate the fraction of animals not eating during the test. The accepted level of significance was set at $p \leq 0.05$.

Results

Metformin does not modify glucose metabolism and emotionally related behaviors in mice fed an STD

In the first part of this study, the effects of 4 weeks of administration of Met, an oral antidiabetic drug displaying insulin-sensitizing properties, were evaluated on metabolism and behavior in mice fed an STD. Comparing STD-Veh ($n = 9$) and STD-Met ($n = 8$) mice using an unpaired *t* test, we found no statistical differences between groups on final body weight (31.5 ± 0.5 vs 30.2 ± 0.6 g; $p = 0.4$), fasting glycemia (122 ± 6 vs 110 ± 4 mg/dl; $p = 0.1$), fasting plasma insulin (1.3 ± 0.3 vs 0.7 ± 0.1 ng/ml; $p = 0.3$), HOMA-IR (0.39 ± 0.09 vs 0.19 ± 0.03 ; $p = 0.1$), and glucose tolerance (AUC_{0-120} : 565 ± 57 vs 597 ± 105 ; $p = 0.4$). Similarly, at the behavioral level, no significant differences were detected between STD-Veh and STD-Met mice regarding their performances in the EPM (time: 69 ± 6 vs 67 ± 11 s, $p = 0.8$; entries in open arms: 7.4 ± 1 vs 7.8 ± 1 s, $p = 0.8$), the NSF (latency to feed: 163 ± 19 vs 202 ± 46 s, $p = 0.5$), and the TST (88 ± 6 vs 78 ± 8 s, $p = 0.4$).

Metformin improves glucose metabolism in mice fed an HFD

We then tested the effects of Met in mice fed an HFD for 16 weeks. Exposure to HFD induced a significantly higher increase in body weight from the 1st to the 12th week than that observed in control mice fed an STD. Before the initiation of the different treatments (12th week), HFD groups of mice were balanced, and the average individual weights were similar (Fig. 1A). Four weeks later (16th week), higher body weight was observed in HFD-Veh relative to control mice fed an STD ($p = 0.0003$; Fig. 1A, B), whereas HFD-Met mice had lower body weight than HFD-Veh mice ($p = 0.02$; Fig. 1A, B). During this period, fluid intake was similar among STD-Veh, HFD-Veh, and HFD-Met mice (Fig. 1C). With respect to the other metabolic measures, an HFD increased fasting glycemia ($p = 0.0001$), insulinemia ($p = 0.0006$), and the HOMA-IR ($p = 0.0004$) relative to controls (Fig. 1D–F). All of these parameters were decreased in HFD-Met mice compared with HFD-Veh mice, albeit not statistically significant for insulinemia ($p = 0.0001$; $p = 0.13$; $p = 0.04$; Fig. 1D–F). In keeping with the latter observations, HFD-Veh mice displayed glucose intolerance ($p = 0.0002$), and this effect was reversed by Met ($p = 0.0002$; Fig. 1G, H). Together, these data show that HFD-fed mice displayed obvious metabolic disturbances, whereas chronic treatment with Met reversed these metabolic impairments through insulin-sensitizing properties.

Figure 5. Chronic administration of metformin modulates 5-HT release in the ventral hippocampus of mice fed an HFD. Two groups of mice were fed an HFD for 16 weeks and were chronically treated with Met (300 mg/kg) or its Veh in the drinking water for the last 4 weeks. The control group of mice was fed a STD and administered the Veh. **A, B**, Data are the mean ± SEM of basal extracellular 5-HT levels in the vHP (pg/15 μ l) on a 0–120 min period ($F_{(2,13)} = 4.5$; $p = 0.03$). **C**, Data are the mean ± SEM of [5-HT]ext levels in vHP, expressed as percentages of the respective basal values following exposure to an intraperitoneal administration of fluoxetine (18 mg/kg). **D**, AUC (mean ± SEM) values calculated for the amount of 5-HT in the vHP outflow measured during the 135–180 min after Flx administration and expressed as percentages of baseline ($F_{(2,13)} = 7.4$; $p = 0.007$). **E**, Coronal sections of a C57BL/6 mouse brain showing the location of the concentric microdialysis probes tips in the hippocampus. The black, gray, and blue lines indicate the brain zone of the membrane from STD-Veh, HFD-Veh, and HFD-Met mice, respectively. * $p < 0.05$: significantly different from the STD-Veh group. ## $p < 0.01$: significantly different from the HFD-Veh group. \$ $p < 0.05$: significantly different from the 100% value.

Metformin decreases plasma levels of BCAAs in mice fed an HFD

Because elevated circulating BCAAs levels have been correlated with the severity of insulin resistance (Gannon et al., 2018) and neurobehavioral abnormalities (Coppola et al., 2013), we measured the plasma levels of these amino acids. As expected, HFD-Veh mice displayed a marked increase in plasma BCAAs ($p = 0.0038$) compared with STD-Veh mice, and this rise in plasma BCAA content was significantly attenuated in HFD-Met mice ($p = 0.0003$; Fig. 2).

Metformin positively influences the serotonergic system in mice fed an HFD

Because BCAAs share the same transport protein into the brain with aromatic amino acids such as tryptophan, the sole precursor of centrally produced 5-HT, we then questioned the impact of these changes in plasma levels of amino acids on the serotonergic system. We first studied the activity of presumed DR 5-HT neurons using *in vivo* electrophysiology. Results indicated that the average number of cells recorded per track was not different among the experimental groups (Fig. 3A). However, although the firing rate of DR 5-HT neurons was not modified in HFD-Veh mice compared with STD-Veh mice, the statistical analysis revealed a significant increase in the firing rate of these neuronal populations in HFD-Met mice compared with HFD-Veh mice ($p = 0.032$; Fig. 3B,C).

Using patch-clamp electrophysiology on brain slices from Pet1-cre-mCherry mice to selectively visualize DR 5-HT neurons (Fig. 4A), we found decreased input resistance in these neurons in HFD-Veh mice compared with STD-Veh mice without modification of the number of spikes evoked by depolarizing currents ($p < 0.0001$; Fig. 4B–D). Met treatment increased the input resistance ($p < 0.0001$; Fig. 4B) and the number of spikes in response to depolarizing currents of 5-HT neurons compared with STD- or HFD-fed mice ($p < 0.0001$; Fig. 4C,D). In HFD-Veh mice, an attenuated response to phenylephrine application was also observed ($p = 0.0006$; Fig. 4E) whereas Met treatment reversed this parameter ($p = 0.0339$). Of particular note are the impairments of some of the intrinsic properties of 5-HT neuron action potentials in HFD-Veh mice, which were partially reversed in HFD-Met mice (Fig. 4F, G). Interestingly, the frequency and amplitude of sEPSCs or sIPSCs in 5-HT neurons was not affected by HFD feeding ($p = 0.7106$ and $p = 0.2220$ for sEPSCs, respectively; $p = 0.9588$ and $p = 0.4888$ for sIPSCs, respectively; Fig. 4H,I). These data suggest that the effects of the diet on the electrical properties of 5-HT neurons were not due to changes in glutamate or GABA presynaptic inputs.

To determine whether changes in electrical properties of DR 5-HT neurons have *in vivo* consequences on basal extracellular 5-HT levels ([5-HT]ext) in the vHP, we conducted intracerebral microdialysis experiments (Fig. 5). This brain region is endowed with a dense serotonergic innervation from the DR and is particularly important in anxiolytic-like/antidepressant-like responses. Basal [5-HT]ext levels were significantly decreased in the HFD-Veh mice ($p = 0.04$) and HFD-Met mice ($p = 0.03$; Fig. 5A,B) compared with STD-Veh mice. Testing the effect of a challenge

dose of Flx to produce an acute inactivation of the serotonin transporter (SERT), we observed that this pharmacological compound significantly increased the percentage of [5-HT]ext over baseline in STD-Veh and HFD-Met mice ($p = 0.013$ and $p = 0.0011$, respectively), but such a response was not apparent in HFD-Veh mice ($p = 0.46$; Fig. 5C,D). Interestingly the neurochemical effect of Flx was higher in HFD-Met than that observed in the other groups (Fig. 5C,D).

Metformin promotes anxiolytic/antidepressant-like activities in mice fed an HFD

Finally, we sought to determine how these properties reverberated at the behavioral level. The SSRI Flx was used as positive control. We first control the locomotor activity of mice using the OF, and we showed that this parameter was not significantly different between groups (Fig. 6A). In the EPM, HFD-Veh mice displayed decreased time ($p = 0.0045$) and entries in open arms ($p = 0.0002$) compared with STD-Veh mice. These anxiogenic-like responses were partially reversed in HFD-Met-treated mice ($p = 0.04$ and $p = 0.09$) but not in HFD-Flx-treated mice ($p = 0.99$ and $p = 0.99$; Fig. 6B,C). In the NSF, an increased latency to feed, which can be also used as a readout for anxiety, was detected in HFD-Veh mice ($p = 0.0001$). This behavior was significantly attenuated in HFD-Met mice ($p = 0.015$) and HFD-Flx mice ($p = 0.0001$) compared with HFD-Veh mice (Fig. 6D). In an attempt to verify that the latter results could not be attributable to changes in hunger, we verified that the latency to eat in the home cage was the same in all experimental groups (Fig. 6E). Interestingly, food home cage consumption based on caloric value consumed was significantly higher in HFD-Veh mice ($p = 0.0001$), HFD-Met mice ($p = 0.0001$), and HFD-Flx mice ($p = 0.0001$) compared with STD-Veh mice (Fig. 6F), thereby reinforcing the idea that the increased latency to eat during the test was not related to the fact that HFD mice were less starved. We also evaluated other symptoms of depression such as despair in the TST. No changes in the time of immobility was detected in HFD-Veh mice ($p = 0.69$) compared with controls. However, we found a decrease of this parameter in HFD-Met mice ($p = 0.04$) and HFD-Flx mice ($p = 0.04$) relative to HFD-Veh mice (Fig. 6G). Overall, these results indicated that mice fed an HFD harbored a robust anxious phenotype. In this model, Met elicited both anxiolytic- and antidepressant-like responses.

BCAA deficiency in diet exerts anxiolytic-/antidepressant-like effects without improvement of glucose metabolism in mice fed an HFD

As Met improves glucose metabolism, decreases plasma BCAA levels, and elicits anxiolytic-/antidepressant-like activities in mice

Figure 6. Chronic administration of metformin reverses HFD-induced anxiety-/depressive-like effects. Three groups of mice were fed an HFD and administered Met (300 mg/kg), or Flx (20 mg/kg) or its Veh in the drinking water for 4 weeks. The control group of mice was fed an STD and administered the Veh. **A–G**, Data are the mean \pm SEM of the total distance traveled in the open field for 10 min [$F_{(3,36)} = 2.8$; $p = 0.06$]; **A**), time spent, and number of entries in open arms in the EPM ($F_{(3,36)} = 6.7$, $p = 0.0011$; and $F_{(3,36)} = 10.2$, $p = 0.0001$); **B, C**), latency to feed in the NSF ($F_{(3,36)} = 22.8$, $p = 0.0001$); **D**), latency to feed in the home cage ($F_{(3,36)} = 0.22$, $p = 0.88$); **E**), food home cage consumption based on caloric value consumed ($F_{(3,36)} = 17.6$; $p = 0.0001$); **F**), and time of immobility in the TST ($F_{(3,36)} = 6.4$; $p = 0.0013$); **G**). $n = 10$ mice/group. ** $p < 0.01$ and *** $p < 0.001$: significantly different from STD-Veh group. # $p < 0.05$, ## $p < 0.01$ and ### $p < 0.001$: significantly different from HFD-Veh group.

fed an HFD, we tested the possibility that deficiency in these specific amino acids could exert beneficial effects both on peripheral parameters and neurobehavioral responses. With this prospect, we designed a modified HFD in which the BCAA dietary supply was reduced by half. The plasma levels of BCAAs was reduced by $\sim 40\%$ in HFD-BCAA^{+/-} mice compared with HFD-BCAA^{+/+} mice ($p = 0.0001$; Fig. 7A).

Exposure to HFD-BCAA^{+/+} for 16 weeks induced a significant increase in body weight, fasting glycemia, and insulinemia ($p = 0.0001$; $p = 0.04$; $p = 0.04$); and resulted in a significant glucose intolerance ($p = 0.0001$) compared with control mice fed an STD (Fig. 7B–G). The same phenotype was observed in HFD-BCAA^{+/-} mice ($p = 0.0001$, $p = 0.008$, $p = 0.04$, and $p = 0.0001$), and no differences between HFD-BCAA^{+/+} and HFD-BCAA^{+/-} mice ($p = 0.73$; $p = 0.63$; $p = 0.99$ and $p = 0.91$; Fig. 7B–G) were detected, showing that the partial deficiency in BCAA is not sufficient to reverse glucose metabolism impairments.

As regards behavioral consequences, we reported that the locomotor activity was similar in the different experimental groups

Figure 7. Partial deficiency in BCAAs does not improve glucose metabolism in mice fed an HFD. Two groups of mice were fed an HFD with a normal or reduced content of branched-chain amino acids (HFD-BCAA^{+/+} and HFD-BCAA^{+/-}; respectively). The control group of mice was fed an STD. **A–G**, Data are the mean \pm SEM of plasma levels of BCAAs (Leu, Val, Iso-Leu; $F_{(2,27)} = 26.1$; $p = 0.0001$; **A**), body weight from week 0 to week 16 (**B**), final body weight ($F_{(2,27)} = 18.8$; $p = 0.0001$; **C**), basal fasting glycemia ($F_{(2,27)} = 5.6$; $p = 0.008$; **D**), basal fasting insulinemia ($F_{(2,27)} = 4.6$; $p = 0.02$; **E**), glucose tolerance in response to the intraperitoneal administration of glucose (2 g/kg; for AUC_{0-120} ; $F_{(2,27)} = 14.7$; $p = 0.0001$; **F, G**). $n = 10$ mice/group. * $p < 0.05$, ** $p < 0.01$ and *** $p < 0.001$: significantly different from STD-Veh group. ### $p < 0.001$: significantly different from HFD-BCAA^{+/+} mice.

(Fig. 8A). In the EPM, HFD-BCAA^{+/+} and HFD-BCAA^{+/-} mice displayed a decrease in time ($p = 0.04$ and $p = 0.03$) and/or entries in open arms ($p = 0.53$ and $p = 0.013$; Fig. 8B, C) compared with STD mice. No differences between HFD-BCAA^{+/+} and HFD-BCAA^{+/-} mice were detected ($p = 0.82$ and $p = 0.12$). In the NSF, although a significant increase in latency to feed was detected in HFD-BCAA^{+/+} and HFD-BCAA^{+/-} mice compared with STD mice ($p = 0.0002$ and $p = 0.0065$; Fig. 8D), both groups displayed similar responses in this paradigm ($p = 0.35$). The latency to eat in the home cage was the same in all experimental groups (Fig. 8E), whereas food home cage consumption based on caloric value consumed was higher in HFD-BCAA^{+/+} and HFD-BCAA^{+/-} mice compared with STD mice, but did not reach statistical significance (Fig. 8F). In the TST, a significant decrease in the time of immobility was detected in HFD-BCAA^{+/-} mice compared with HFD-BCAA^{+/+} mice ($p = 0.021$; Fig. 8G). Finally, we showed a higher latency of first grooming in HFD-

BCAA^{+/+} mice ($p = 0.04$) but not in HFD-BCAA^{+/-} mice ($p = 0.61$) compared with STD mice in the ST, and a significant difference was observed between the latter groups ($p = 0.019$; Fig. 8H). Together, these results led us to envision that deficiency in BCAA might exert antidepressant-like properties while maintaining a high level of anxiety.

In a last series of experiments, we asked how such deficiency in amino acids impacts the response to an acute administration of Flx in the TST. A few days after the first session of TST, we resubmitted the same animals to this procedure and found that a single administration of Flx significantly decreased the percentage of time of immobility in controls ($p = 0.03$) but not in HFD-BCAA^{+/+} mice ($p = 0.37$; Fig. 9). The antidepressant-like effect of Flx was fully restored in HFD-BCAA^{+/-} mice ($p = 0.009$; Fig. 9).

Discussion

This study was designed to determine the neurobehavioral effects of Met in mice fed an HFD and to decipher its putative mechanism of action focusing on the serotonergic system and its projections to the hippocampus, a brain region morphologically and functionally affected in major depression (MacQueen and Frodl, 2011). One of the most remarkable results reported herein is the fact that HFD-induced peripheral IR was accompanied by elevated levels of circulating BCAAs. In the CNS, HFD impaired both the electrical properties of DR 5-HT neurons and 5-HT release, resulting in altered emotionally related behaviors, whereas Met improved all these peripheral and central parameters. Because changes in plasma BCAAs are known to limit tryptophan availability into the brain, we also provided evidence that partial deficiency of BCAAs in diet is sufficient to exert antidepressant-like activity.

It is now well accepted that in homogenous C57BL/6J mice, HFD feeding leads to IR (Burcelin et al., 2002). In agreement with this finding, we reported that exposure to an HFD for 16 weeks elicits glucose metabolic impairments. Met, which belongs to a class of insulin-sensitizing drugs, significantly decreased body weight and improved peripheral IR in mice fed an HFD. Its beneficial effects on peripheral metabolism have been attributed to several peripheral processes including the activation of AMP-activated protein kinase (AMPK) pathway, reduction in hepatic gluconeogenesis, and stimulation of glucose uptake in skeletal muscle (Graham et al., 2011). Interestingly, increased IR drives higher circulating fasting BCAA levels (Mahendran et al., 2017), while rats fed a diet high in BCAAs displayed increased rates of IR (Newgard et al., 2009; Zhao et al., 2016). Here, we demonstrated that HFD mice displayed elevated plasma levels of BCAAs, whereas Met reversed this parameter. Interestingly, 5-HT synthe-

sis in neurons can be influenced by tryptophan uptake into the brain, which occurs through the LAT1 on the BBB that it shares with the BCAAs (Yamamoto and Newsholme, 2000; Fernstrom, 1983, 2013). Thus, we hypothesized that chronic exposure to an HFD could raise plasma BCAA concentrations sufficiently to limit the uptake of tryptophan into the brain as a result of the competition between amino acids, and thereby reduce neuronal 5-HT synthesis and release from nerve terminals. This is consistent with findings reporting that supplementation in BCAAs reduced brain 5-HT content in rats (Choi et al., 2013) and induced depressive-like symptoms in rodents such as anxiety (Coppola et al., 2013) or anhedonia (Scaini et al., 2014). By attenuating circulating BCAA levels, Met could favor tryptophan availability in the brain and thereby positively reverberate on central 5-HT tone. In an attempt to confirm this assumption and to provide a more valuable insight into the impact of the modulation of circulating BCAAs on the activity of the serotonergic system, electrophysiological and microdialysis experiments were conducted.

In vivo electrophysiological experiments indicated that an HFD did not modify the basal firing rate of DR 5-HT neurons, whereas patch-clamp recordings pointed out that the intrinsic properties of these neurons were significantly impaired. It is plausible that the altered excitability observed in patch-clamp recordings would not affect the basal firing rate but would rather limit DR neuron activation in response to diverse stimuli that notably increased norepinephrine release, which is known to accelerate the pacemaker activity of 5-HT neurons in an $\alpha 1$ adrenoceptor-dependent manner (Aghajanian, 1985). Accordingly, we found that the phenylephrine-induced increased firing rate is blunted after HFD feeding. Met increased the firing rate of DR 5-HT neurons and reversed the impairments of electrical parameters detected in HFD mice. These electrophysiological data parallel the altered extracellular 5-HT levels ($[5\text{-HT}]_{\text{ext}}$) in the vHP of mice fed an HFD. Indeed, using *in vivo* microdialysis, we reported a twofold decrease in basal extracellular $[5\text{-HT}]_{\text{ext}}$ in HFD mice. However, Met failed to reverse this neurochemical response. Because 5-HT outflow measured by microdialysis reflects a balance between 5-HT uptake and release (Guiard et al., 2006), we assumed that any increase in 5-HT release at the nerve terminals may be counterbalanced by an active 5-HT reuptake process. If this assumption is correct, the stimulating effects of Met on basal extracellular 5-HT levels would be revealed in the presence of a SERT inhibitor. Accordingly, we showed that the acute administration of Flx elicited a greater increase in hippocampal $[5\text{-HT}]_{\text{ext}}$ in HFD-Met mice than in HFD-Veh.

We next questioned the effects of Met on anxiety- and depressive-like phenotypes, which are finely regulated by 5-HT

Figure 8. Partial deficiency in BCAAs promotes antidepressant-like effects in mice fed an HFD. Two groups of mice were fed an HFD with a normal or reduced content of branched-chain amino acids (HFD-BCAA^{+/+} and HFD-BCAA^{+/-}, respectively). **A–H**, The control group of mice was fed an STD. Data are the mean \pm SEM of total distance traveled in the open field for 10 min ($F_{(2,27)} = 0.3$; $p = 0.74$; **A**), time spent and the number of entries in open arms ($F_{(2,27)} = 4.4$, $p = 0.02$; and $F_{(2,27)} = 4.7$, $p = 0.016$; **B**, **C**), latency to feed in the novelty suppressed feeding ($F_{(2,27)} = 11.9$, $p = 0.0002$; **D**), latency to feed in the home cage ($F_{(2,27)} = 1.4$, $p = 0.25$; **E**), food home cage consumption based on caloric value consumed ($F_{(2,27)} = 1.2$, $p = 0.3$; **F**), time of immobility in the tail suspension test ($F_{(2,27)} = 4.2$, $p = 0.025$; **G**), and latency of first grooming in the splash test ($F_{(2,27)} = 4.5$, $p = 0.02$; **H**). $n = 10$ mice/group. * $p < 0.05$, ** $p < 0.01$ and *** $p < 0.001$: significantly different from STD-Veh group. # $p < 0.05$: significantly different from HFD-BCAA^{+/+} mice.

Figure 9. Partial deficiency in BCAAs restores normal response to the antidepressant fluoxetine in mice fed an HFD. Two groups of mice were fed an HFD with a normal or reduced content of branched-chain amino acids (HFD-BCAA^{+/+} and HFD-BCAA^{+/-}, respectively). The control group of mice was fed an STD. Data are the mean \pm SEM of the percentage time of immobility relative to the corresponding control group of mice injected with NaCl 0.9% in the tail suspension test. Mice were tested 30 min after the intraperitoneal administration of NaCl 0.9% (–) or Flx (18 mg/kg; two-way ANOVA: $F_{(2,54)} = 2.3$, $p = 0.65$; and $F_{(1,54)} = 30.2$, $p = 0.0005$ for diet and treatment factors, respectively). $n = 10$ mice/group. * $p < 0.05$ and ** $p < 0.01$: significantly different from the corresponding group of mice injected with NaCl 0.9%.

Figure 10. Model underpinning the effects of metformin on depressive symptoms in mice fed an HFD. Peripheral insulin resistance has been associated with anxiogenic-like response, one of the most visible and early symptoms of depression. This metabolic impairment is also responsible for an increase in plasma BCAA (Val, Leu, Isoleu) levels, which limit tryptophan availability in DR 5-HT neurons due to a lower brain penetration across LAT1 expressed on the BBB. **A**, Such effects are believed to impair DR 5-HT neuronal activity and 5-HT release at the nerve terminals, thereby leading to despair, another symptom of depression. The ability of Met to ameliorate insulin sensitivity represents an important process to promote anxiolytic effects whereas its antidepressant-like effects could rely on both direct (i) and indirect (ii) mechanisms converging toward lower levels of circulating BCAAs. **B**, The latter mechanism would favor 5-HT neuronal activity and 5-HT release at the nerve terminals, which are key for the antidepressant response. Owing to an active 5-HT reuptake process in the hippocampus of HFD mice treated with Met, the association of this antidiabetic drug with an SSRI could be a new potentiation strategy exerting a wide spectrum of action. Alternatively, the combination of SSRI with a diet poor in BCAAs might be used to relieve depressive symptoms in depressed patients with or without comorbid metabolic disorders.

projections. Our results indicate that mice fed an HFD are prone to develop anxiety, as shown in the EPM and NSF. This result is particularly interesting since anxiety manifests as a predominant feature of depression and can also precede the onset of the pathology (Malhi and Mann, 2018). In a marked contrast, HFD did not influence the time of immobility in the TST, but this result does not rule out the possibility that such a diet caused depressive symptoms beyond anxiety. Indeed, the TST and the forced swim stress have been developed to screen antidepressant-like activity rather than to ascertain depressive-like behavior (Nestler and

Hyman, 2010). The observation that HFD leads to anhedonia and decreased self-care (Dutheil et al., 2016; Zemdegs et al., 2016) reinforces the idea that core symptoms of depression can be also affected by HFD-induced IR (Miyata et al., 2004; Abildgaard et al., 2011; Ho et al., 2012; André et al., 2014; Gupta et al., 2014; Liu et al., 2014; Dutheil et al., 2016; Yang et al., 2016; Zemdegs et al., 2016; Hassan et al., 2018). These data mirror the clinical observations that people experiencing type 2 diabetes and IR are twice as likely to develop depression compared to people without diabetes (Anderson et al., 2001; de Groot et al., 2001). Interestingly,

the improvement of metabolic parameters induced by prolonged administration of Met in mice fed an HFD were accompanied by a reduction of both anxiety and despair, whereas fluoxetine, the conventional antidepressant drug used herein as a positive control, failed to exert beneficial effects in the EPM. These results concur with previous preclinical studies pointing out that different classes of antidiabetic agents or adiponectin, a hormone exerting insulin-sensitizing action, produces antidepressant-like activities (Ho et al., 2012; Liu et al., 2012; Gupta et al., 2014; Su et al., 2017). In humans, a recent study also reported that Met favors depression recovery in patients with comorbid diabetes unveiling a strong correlation between improvement in plasma glycated hemoglobin levels and depression score (Guo and Lu, 2014).

In light of the latter results, we generated an HFD with a partial deficiency in BCAAs (i.e., HFD-BCAA^{+/-}) for which a significant reduction of these plasma amino acids content by 40% was detected. As previously reported, we found that an HFD deficient in BCAAs did not display an improvement of peripheral IR (White et al., 2016), but reduced despair, and improvement of self-care was detected in HFD-BCAA^{+/-} mice. Finally, we investigated to what extent HFD-BCAA^{+/-} influences the response of a single administration of Flx in the TST. Although acute administration of Flx failed to exert an antidepressant-like effect in HFD-BCAA^{+/+} mice, a normal response was observed in HFD-BCAA^{+/-} mice. The efficacy of antidepressant drugs in a context of T2D and IR both in humans and rodents has been subjected to only few investigations, and no consistent conclusions have been provided (Anderson et al., 2010; Bryan et al., 2010; Isingrini et al., 2010; Gois et al., 2014; Zemdegs et al., 2016).

The present study proposes a new antidepressant strategy based on chronic treatment with Met, which acts, at least in part, by reducing circulating levels of BCAAs and by stimulating 5-HT release in the vHP (Fig. 10). It is important to emphasize that an improvement of brain IR could represent another mechanism underlying the beneficial action of Met. Indeed, the brain is endowed with a high density of insulin receptors (Kleinriders et al., 2014), and growing evidence emphasizes their role in the regulation of brain monoaminergic transmission (Kleinriders et al., 2015) and signaling (Papazoglou et al., 2015). It should also be borne in mind that Met crosses the BBB and has several beneficial effects in the brain such as anti-inflammatory and neuroprotective effects (Łabuzek et al., 2010). A possible mechanism underpinning the anxiolytic- and antidepressant-like effects of Met could thus also recruit such properties. Overall, this study supports the fact that the association of Met or a diet poor in BCAAs with an SSRI could be a relevant “add-on” strategy for the comorbidity of metabolic and mental disorders. This hypothesis has been recently tested showing that the association of Flx and Met produced greater improvement of depressive symptoms in rats exposed to chronic stress and an HFD (Khedr et al., 2018). In light of these data, clinical and preclinical studies are also warranted to further evaluate the efficacy of such a potentiation strategy in depressed patients or in relevant animal models without metabolic comorbidities. In this prospect, a recent study shows that Met produces antidepressant-like activities given either alone (Liu et al., 2019) or in combination with Flx (Poggini et al., 2019) in chronically stressed animals.
