**Abstract:** Seabirds from remote regions are mainly exposed to environmental contaminants from non-point contamination of their food webs. Pre-fledging seabird chicks are fed by their parents with marine prey captured in the vicinity of breeding colonies. Contaminant concentrations in tissues of pre-fledging chicks can thus be mostly related to local dietary sources, and have the potential to unravel spatial patterns of environmental contamination in marine ecosystems. Here, mercury (Hg), 13 other trace elements, and 18 persistent organic pollutants (POPs) were quantified in blood of chicks across four breeding locations that encompass a large latitudinal range in the southern Indian Ocean (from Antarctica, through subantarctic areas, to the subtropics), over a single breeding season. Thirteen species of penguins, albatrosses and petrels were studied, including endangered and near-threatened species, such as Amsterdam albatrosses and emperor penguins. Blood Hg burdens varied widely between species, with a factor of ~50 between the lowest and highest concentrations (mean  $\pm$  SD,  $0.05 \pm 0.01$  and  $2.66 \pm 0.81 \mu\text{g g}^{-1}$  dry weight, in thin-billed prions and Amsterdam albatrosses, respectively). Species relying on Antarctic waters for feeding had low Hg exposure. Concentrations of POPs were low in chicks, with the exception of hexachlorobenzene. Contaminant concentrations were mainly explained by species differences, but feeding habitat (inferred from  $\delta^{13}\text{C}$  values) and chicks' body mass also contributed to explain variation. Collectively, our findings call for further toxicological investigations in Amsterdam albatrosses and small petrel species, because they were exposed to high and diverse sources of contaminants, and in macaroni penguins, which specifically showed very high selenium concentrations.

**Key words:** Albatrosses; blood; mercury; penguins; petrels; selenium; stable isotopes.

**Capsule:** Seabird chicks from four distant sites in the southern Indian Ocean had contrasted blood metallic and organic contaminant patterns depending on species, feeding habitat and body mass.

### **Highlights**

- Blood trace elements and POPs were measured in southern Indian Ocean seabird chicks
- Latitudinal trends in chicks' blood burdens were evident for Hg
- Amsterdam albatrosses and macaroni penguins had high Hg and Se burdens, respectively
- Small petrels had high and diverse blood POPs concentrations

### **1. Introduction**

Human activities have disrupted the natural cycles of both essential and non-essential metals (Outridge et al., 2018; Sen and Peucker-Ehrenbrink, 2012). In addition, synthetic compounds including legacy and emerging organic pollutants are still intentionally and non-intentionally released into the environment (van den Berg et al., 2017). Trends and effects of environmental contaminants in abiotic and biotic matrices have been extensively studied in the Northern Hemisphere, while data is much scarcer in the Southern Hemisphere (Outridge et al., 2018; UNEP, 2019; van den Berg et al., 2017). Southern Hemisphere countries have recently experienced increases in mercury (Hg) emissions from artisanal and small-scale gold mining (Eagles-Smith et al., 2018; UNEP, 2019), and are exempt from some Stockholm Convention restrictions to the use of persistent organic pollutants (POPs) such as DDT for malaria fighting (van den Berg et al., 2017). This could influence large-scale transport and deposition of contaminants in oceanic waters, which cover a great portion of this hemisphere. Yet, ecotoxicological and biogeochemical studies in Southern Hemisphere oceanic waters are dramatically lacking. Apart from localised point pollution from large research stations (Wild et

al., 2015), oceanic waters surrounding far-removed archipelagos, such as those found in the southern Indian Ocean, are free from significant, local sources of chemical compounds. Quantifying contaminant exposure to living organisms from these areas can thus substantially contribute to filling the gap in our understanding of spatiotemporal trends of environmental contamination in the Southern Hemisphere.

Seabirds are particularly suitable to study spatiotemporal trends of contamination in remote marine environments because they are easily accessible during reproduction on land, and display high fidelity to breeding and feeding sites (Burger and Gochfeld, 2004; Elliott and Elliott, 2013). Seabirds are mainly exposed to environmental contaminants through food ingestion, and thus integrate the contamination of their food webs (Borgå et al., 2004; Lavoie et al., 2013). In the last decades there has been an increased interest in the bioaccumulation of metallic and organic compounds in Southern Hemisphere seabirds (Becker et al., 2016; Brasso et al., 2015; Finger et al., 2016). While taking into account the dietary drivers of exposure, some studies on emblematic species have revealed previously ignored geographical patterns of contaminant abundance in Southern Ocean food webs (Carravieri et al., 2014b; Roscales et al., 2016), providing guidance for biogeochemical efforts. Multi-specific studies of contaminant exposure over large oceanic regions are very powerful (Becker et al., 2016; Polito et al., 2016). First, they have the potential to give an integrative picture of contaminant patterns across different trophic levels (Anderson et al., 2010; Becker et al., 2016; Carravieri et al., 2014c). Second, they are necessary to quantify natural variation in essential element concentrations, which is drastically understudied (Anderson et al., 2010; Finger et al., 2016). Third, they can help us identify good bioindicator species for spatiotemporal monitoring of concentrations, and insights into the biogeochemical behaviour of specific contaminants (Hg stable isotopes, Renedo et al., 2018a). Finally, they can reveal risk of potential toxic effects in particular species. However, carrying out multi-specific investigations over large spatial scales in remote

environments is logistically challenging. In addition, data collection over different time periods may result in a temporal bias in the measured contaminant concentrations. Multi-specific studies in seabirds have so far focused mainly on adult individuals (Anderson et al., 2010, 2009; Becker et al., 2016; Roscales et al., 2016, but see Blévin et al., 2013; Sebastiano et al., 2017), where tissue contaminant concentrations are governed by a complex mixture of intrinsic (age, sex, breeding status, Borgå et al., 2004; Lerma et al., 2016) and extrinsic (migration over large distances or season, e.g., Finger et al., 2016; Leat et al., 2013) factors that can limit our capacity to identify specific sources of exposure. By contrast, pre-fledging seabird chicks (hereafter chicks) are fed by their parents with marine prey captured in the vicinity of breeding colonies. In fully-grown chicks, influence of *in ovo* exposure after maternal transfer of contaminants into the egg is negligible (Bourgeon et al., 2013), because of the growth dilution effect or/and excretion into feathers (Ackerman et al., 2011). Concentrations in their tissues are thus mainly representative of local exposure over a limited time window (the chick-rearing period). In addition, flightless chicks are more accessible than adults, and tissues such as blood and feathers can be easily and quickly sampled at the nest (e.g., during ringing sessions, Carravieri et al., 2014a). Therefore, chicks are excellent candidates to evaluate contaminant exposure in several species across multiple breeding sites.

The present study focusses on chicks of 13 seabird species (three *Eudyptes* sp.; two *Aptenodytes* and *Pygoscelis* sp.; one *Diomedea*, *Halobaena*, *Pachyptila*, *Pagodroma*, *Procellaria*, and *Thalassarche* sp., Table S1) breeding at four sites over a large latitudinal gradient in the southern Indian Ocean, from Antarctic to subtropical waters (Fig. S1). At these sites, chick diet has been relatively well-studied (Table S1), and includes marine prey ranging from crustaceans to fish and cephalopods, encompassing multiple trophic levels. This work complements a recent investigation in chicks of *Catharacta* species (Carravieri et al., 2017) and its specific objectives were 1) to quantify blood contaminant concentrations (14 essential and

non-essential trace elements and 18 legacy-persistent organic pollutants, POPs) in the 13 species, including previously undocumented and endangered ones, , 2) to unravel species- and dietary-related differences in exposure, by using the isotopic niche as a proxy of the trophic niche (Newsome et al., 2007), 3) to confirm previously shown geographic patterns of contamination, and 4) to identify good bioindicator species for long-term monitoring. We expected (i) stronger inter-specific differences in non-essential trace element and POP patterns, than in essential trace elements that are physiologically regulated (Walker et al., 2012); (ii) chicks to have increasing blood Hg concentrations from Antarctic to subtropical environments (Carravieri et al., 2017, 2014c, 2014b; Cherel et al., 2018); and (iii) all chicks to bear low concentrations of POPs when compared to Northern Hemisphere species, with the exception of HCB (Bengtson Nash et al., 2007; Carravieri et al., 2014b).

## **2. Material and methods**

### *2.1. Study sites and sampling procedure*

Fieldwork was conducted at four sites that lie in different water masses of the southern Indian Ocean (Fig. S1): Adélie land (66°40'S, 140°01'E) in high-Antarctica, Kerguelen (49°21'S, 70°18'E) and Crozet Archipelagos (46°26'S, 51°45'E) in the subantarctic zone *sensus lato* (between the Polar Front and the Subtropical Front), and Amsterdam Island (37°50'S, 77°31'E) in the subtropics (north of the Subtropical Front). Well-feathered chicks were captured by hand before fledging during the 2011-2012 breeding season at all sites (N = 139 in total, n = 9-14 individuals per species, Table 1). Blood (1.5 to 6 mL depending on species size) was sampled from the brachial vein with heparinized syringes. Whole blood was centrifuged less than 2 hours after sampling, and blood cells and plasma were stored at -20 °C until laboratory analyses in France.

### *2.2. Trace element, POP and stable isotope analyses*

Blood is increasingly used to quantify contaminant burdens in seabirds. Trace elements partition preferentially in red blood cells (Friberg et al., 1985), while POPs are mainly associated with plasma lipids (Keller et al., 2004; Matthews et al., 1984). Trace elements were measured at the laboratory LIENSs, La Rochelle, France, from lyophilized red blood cells. Total Hg was quantified with an Altec AMA 254 spectrophotometer (limit of detection, LOD, 0.005  $\mu\text{g g}^{-1}$  dry weight, dw; aliquot mass: 5-10 mg dw) following Bustamante et al. (2006). Arsenic (As), chromium (Cr), copper (Cu), iron (Fe), manganese (Mn), nickel (Ni), selenium (Se) and zinc (Zn) were analysed using a Varian Vista-Pro ICP-OES (LOD, ranging from 0.02 (Cr) to 3.3 (Fe, Zn)  $\mu\text{g g}^{-1}$  dw) and silver (Ag), cadmium (Cd), cobalt (Co), lead (Pb) and vanadium (V) using a Thermo Fisher Scientific X Series 2 ICP-MS (LOD ranging from 0.015 (Cd) to 0.3 (V)  $\mu\text{g g}^{-1}$  dw), following Kojadinovic et al. (2011) (aliquots mass: 20-200 mg dw). POPs were measured in plasma (300  $\mu\text{l}$  aliquots) at the laboratory EPOC-LPTC, Bordeaux, France by gas chromatography coupled with electron capture detection (GC-ECD) (Tapie et al., 2011). Seven PCBs (CB-28, -52, -101, -118, -138, -153 and -180; limit of quantification, LOQ, ranging from 0.1 (CB-180) to 1.8 (CB-52)  $\text{ng g}^{-1}$  wet weight, ww) and 11 OCPs (HCB,  $\gamma$ -HCH, heptachlor, 2,4'-DDE, 4,4'-DDE, *cis*-chlordane, *trans*-nonachlor, 4,4'-DDD, 2,4'-DDT, 4,4'-DDT, Mirex; LOQ ranging from 0.05 (heptachlor, *trans*-nonachlor) to 0.6 (HCB)  $\text{ng g}^{-1}$  ww) were targeted. CB-28 and CB-50 co-eluted in all samples, and are reported as CB-28/50. Quality assurance and quality control, as well as LODs and LOQs for all trace elements and POPs are described in the [Supplementary Information](#).

Blood  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  stable isotope ratios were determined at the laboratory LIENSs in red blood cells with a continuous flow mass spectrometer (Thermo Scientific Delta V Advantage) coupled to an elemental analyser (Thermo Scientific Flash EA 1112) (aliquots mass:  $\sim 0.3$  mg dw). Results are in  $\delta$  notation relative to Vienna PeeDee Belemnite and

atmospheric N<sub>2</sub> for  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ , respectively. Measurement errors were  $< 0.15 \text{ ‰}$  for both  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values.

Results are given as mean  $\pm$  SD in  $\mu\text{g g}^{-1}$  dw for trace elements, in  $\text{ng g}^{-1}$  ww for POPs, and in ‰ for stable isotope values. “Blood” within the text refers either to red blood cells for trace element and stable isotope values, or plasma for POP values.

### *2.3. Statistical analyses*

All statistical analyses were performed in the R environment ([R Core Team, 2018](#)). First, in order to explore contaminant co-variance and between-specific differences in concentrations, a principal component analysis (PCA) was carried out on log-transformed, scaled trace elements and POPs with detection frequencies (DF)  $> 70\%$ . Observations below the LOQ were substituted with values drawn randomly from the range  $[0; \text{LOQ}]$ . Second, generalised linear (GLM) multifactorial models were used to quantify the effect of species, feeding habitat (inferred from  $\delta^{13}\text{C}$  values) and their interaction (species: $\delta^{13}\text{C}$ ), on trace elements and POPs. We used forward selection and the Akaike's Information Criterion corrected for small sample sizes (AICc) to identify the best models. The effect of explanatory variables was inferred through Akaike's weights ([Burnham and Anderson, 2002](#)). Model specification and validation were based on residual analysis ([Zuur et al., 2009](#)). To evaluate between-species variation in contaminant concentrations, we applied post-hoc Tukey's honestly significant difference (HSD) tests on the selected models. Some trace elements (Cd, Mn) had qf below 70% overall, but were quantified in most individuals of some species. For those elements, between-species differences were quantified through a linear model (Cd/Mn  $\sim$  Species) on log-transformed values to meet normality and homoscedasticity of residuals, followed by Tukey's HSD. Since different species were sampled at each location, the site effect on contaminant concentrations is confounded by the species effect. Site was thus not included as an explanatory variable, and its effect on contaminant concentrations was described qualitatively. Nevertheless,  $\delta^{13}\text{C}$  values already

function as a reliable proxy of feeding habitat in the southern Indian Ocean, where they increase latitudinally from Antarctic to subantarctic through to subtropical oceanic waters (Cherel and Hobson, 2007; Jaeger et al., 2010). Finally, the  $\delta^{15}\text{N}$  proxy was not included as an explanatory variable in multifactorial analyses because of the large variation in baseline  $\delta^{15}\text{N}$  values in food webs found across the latitudinal range of the four sites (Jaeger et al., 2010). However, blood  $\delta^{15}\text{N}$  values were used in conjunction with  $\delta^{13}\text{C}$  values to quantify the isotopic niches of the 13 species and confirm that they corresponded to previously published results (Table S1). ANOVA F tests were applied to blood  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  raw values separately to test for between-species differences. In addition, we used the Stable Isotope Bayesian Ellipses in R package (SIBER, Jackson et al., 2011) on centred and rescaled isotopic values to draw species-specific bivariate ellipses.

### 3. Results

#### 3.1. Trace element, POP and stable isotope values

Among essential elements, Cu (overall range: 0.29-2.11  $\mu\text{g g}^{-1}$  dw), Fe (1575-2662  $\mu\text{g g}^{-1}$  dw), Se (2.71-237  $\mu\text{g g}^{-1}$  dw), and Zn (18-46  $\mu\text{g g}^{-1}$  dw) were quantified in all individuals (Table 1), while Co, Cr, Ni, V were detected in a very few chicks or none (Table S2). Mn had a relatively high occurrence (qf = 55%, overall range: 0.10-0.78  $\mu\text{g g}^{-1}$  dw, Table S2), but some species had no detectable levels, notably emperor penguins and Amsterdam albatrosses. As was quantifiable in white-chinned and snow petrels (Table S2) and in few individuals of other species. Among non-essential elements, only Hg had a qf of 100% (overall range: 0.03-4.40  $\mu\text{g g}^{-1}$  dw). Cd was notably abundant in subantarctic petrel species, with the highest concentrations found in blue petrels ( $0.41 \pm 0.19$   $\mu\text{g g}^{-1}$  dw, Table S2). Ag and Pb were detected in no or very few individuals, respectively (Table S2).

Of the 14 targeted POPs, only HCB was quantified in more than 70% individuals (overall range: <0.06-2.07 ng g<sup>-1</sup> ww, [Table 1, S3](#)). All PCBs, chlordanes, Mirex and DDT metabolites had qf below 15%, except 4-4'-DDE (DF = 36%), which was quantified in most individuals of blue and white-chinned petrels, thin-billed prions and yellow-nosed and Amsterdam albatrosses, being highest in the latter ( $0.82 \pm 1.10$  ng g<sup>-1</sup> ww, [Table S3](#)). Blue petrels, thin-billed prions and Amsterdam albatrosses also had quantifiable levels of trans-nonachlor ([Table S3](#)). The Amsterdam albatross was also the only species where most individuals had quantifiable levels of 4-4'-DDT ( $0.46 \pm 0.38$  ng g<sup>-1</sup> ww, [Table S3](#)), and of CB-180 ([Table S3](#)). CB-28/50 was quantified in some emperor, king and gentoo penguins ([Table S3](#)).

Blood  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values varied widely among chicks (ANOVA,  $F_{12,126} = 678$  and 508 for  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values, respectively, both  $p < 0.0001$ ). All species occupied different isotopic niches, as shown by non-overlapping standard ellipses areas ([Fig. 1](#)).

### *3.2. Inter-contaminant patterns*

The contaminants included in the PCA were Cu, Fe, Hg, Se, Zn, and HCB. Cu, Hg and Zn contributed most to PC1, while PC2 was governed mainly by Fe, Se and HCB ([Table S4](#)). The PCA did not highlight clear, strong associations among elements ([Fig. 2](#)), nor did preliminary univariate analyses (data not shown). Most species were clearly separated in the ordination space, while others overlapped substantially, irrespective of their breeding site. For example, thin-billed prions and blue petrels from subantarctic environments and snow petrels from Antarctica had a similar pattern of high blood Se and HCB, and low blood Cu and Hg concentrations. Similarly, Adélie penguins (Antarctica) and southern (subantarctic) and northern rockhopper penguins (subtropics) had high blood Fe and low blood HCB concentrations. All the contaminants included in the PCA were retained for subsequent

multifactorial analyses, because they all had PC loadings on PC1 or PC2 of 0.47 or more (Table S4).

### 3.3. Intrinsic and extrinsic drivers of Hg, other trace element and HCB concentrations

Multifactorial analyses indicated that species was a strong predictor of trace element and HCB concentrations in chicks of penguins, albatrosses and petrels. Blood  $\delta^{13}\text{C}$  values and body mass of chicks were also important drivers of element patterns, since models that included them in addition to species had high support in the selection procedure ( $\Delta\text{AICc} < 4$ , Table S5). Namely, the model including species,  $\delta^{13}\text{C}$  values, and their interaction was the best in predicting blood Hg concentrations, and explained a very high proportion of deviance (93%, Table S5). Overall, blood Hg concentrations increased with increasing  $\delta^{13}\text{C}$  values, with the exception of gentoo penguin chicks, where blood Hg and  $\delta^{13}\text{C}$  values were negatively related (Fig. 3). Blood Hg concentrations were lowest in thin-billed prions, intermediate in subantarctic and subtropical penguins, and highest in the Amsterdam albatross (Table 1, Fig. 4). In contrast to Hg, species alone was the main predictor of blood Se concentrations (Tables S5, S6). Penguin species had low Se concentrations ( $<10 \mu\text{g g}^{-1} \text{dw}$ ) with the remarkable exception of macaroni penguins, which had the highest burden of the dataset (Table 1, Fig. 4). Interspecific patterns were different for Hg and Se concentrations, which resulted in a very large range of Se:Hg ratios (Table 1). The lowest Se:Hg ratios were reported in king, gentoo and emperor penguins, and in the Amsterdam albatross, while thin-billed prions and blue petrels had the highest ratios (Table 1).

Interspecific differences (Fig. 4) were clear also for essential element concentrations with relatively low variation across species, such as Cu, Fe and Zn (see small factors between the species with the highest and lowest blood concentrations, Table 1). Emperor penguins, snow, thin-billed and blue petrels had lower and less variable Cu concentrations than most other

species (Fig. 4). Yellow-nosed and Amsterdam albatrosses had the lowest blood Fe concentrations among all species (Fig. 4). Interestingly, chick body mass clearly contributed to explain blood Zn concentrations, as shown by relatively high Akaike's weight (Table S6), with concentrations decreasing with increasing body mass (Fig. S2).

Blood HCB varied by a factor of 15 between the lowest (northern rockhopper penguins) and highest concentrations (thin-billed prions, Table 1). Overall, penguins had low HCB concentrations ( $<0.20 \text{ ng g}^{-1} \text{ ww}$ ) with the exception of king penguins, while small petrels and Amsterdam albatrosses had the highest burdens (Table 1, Fig. 4).

#### 4. Discussion

The present work is the first report of i) Ag, As, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, V, Zn and legacy POPs of thin-billed prions, and the endangered yellow-nosed and Amsterdam albatrosses; ii) legacy POPs in blue petrels, and king, macaroni and northern rockhopper penguins; iii) blood Hg in emperor penguins; iv) blood Ag, As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Se, V, and Zn in all penguin species.

Isotopic results of the present study are overall in accordance with previous work on chicks of the same populations (Table S1). Four points are worth noting: 1) chick blood  $\delta^{13}\text{C}$  values increased from Antarctic, to subantarctic, up to subtropical sites, according to the latitudinal  $\delta^{13}\text{C}$  increase in particulate organic matter from surface waters (Francois et al., 1993) that is reflected in the tissues of marine predators (Cherel and Hobson, 2007; Jaeger et al., 2010); 2) blood  $\delta^{13}\text{C}$  values in gentoo penguins were higher than predicted by the latitudinal  $\delta^{13}\text{C}$  increase because their prey were captured during both pelagic and benthic dives in neritic waters, where baseline  $\delta^{13}\text{C}$  values are higher than in oceanic waters (Cherel and Hobson, 2007; Fig. 1); 3) yellow-nosed albatross chicks had surprisingly higher  $\delta^{15}\text{N}$  values than Amsterdam albatross chicks, but the diet of the latter is unknown (probably large fish and cephalopods;

Cherel et al. 2017); 4) blue petrels and thin-billed prions from the subantarctic Kerguelen Islands foraged in both subantarctic and Antarctic waters when feeding their chicks, thus explaining their low blood  $\delta^{13}\text{C}$  values and why they were classed among Antarctic feeding species in our figures.

#### 4.1. Comparison to previous work on trace elements and POPs in seabird blood

Most ecotoxicological studies in seabirds focus on adults, where concentrations are usually higher than in chicks (Sebastiano et al., 2017, 2016; Renedo et al., 2018). This prevents direct comparison between age-classes, so here we focus on chicks' comparisons. The range of Hg concentrations of the 13 focal species was extremely wide.. Namely, small petrels and rockhopper penguins had low blood Hg concentrations ( $<0.10 \mu\text{g g}^{-1} \text{ dw}$ ) comparable to those found in chicks of most Northern Hemisphere species (Bond and Diamond, 2009; Kahle and Becker, 1999; Lerma et al., 2016). Chicks of larger penguins, petrels and yellow-nosed albatrosses had intermediate concentrations ( $0.80\text{-}1.00 \mu\text{g g}^{-1} \text{ dw}$ ), comparable to Magnificent frigatebirds *Fregata magnificens* (Sebastiano et al., 2016) and great skuas *Stercorarius skua* (Bearhop et al., 2000). Finally, Amsterdam albatross chicks had very high Hg concentrations similar to those found in the sympatric brown skua *Catharacta lonnbergi*, which has the highest known concentration documented so far in wild bird chicks (Carravieri et al., 2017). Non-essential elements other than Hg were overall under detection limits. Yet, Cd was quantified in blue, thin-billed and white-chinned petrels at relatively high concentrations when compared to other studies in chicks and adults (Anderson et al., 2010; Sebastiano et al., 2016, but see Carvalho et al., 2013). This is likely related to Cd-enriched prey such as the hyperiid amphipod *Themisto gaudichaudii*, which is used to feed the chicks (Table S1).

Overall, concentrations of essential elements were in the same range of those found in seabirds worldwide, in both adults and chicks (Cu: range  $0.5\text{-}1.0 \mu\text{g g}^{-1} \text{ dw}$ ; Fe: range 2200-

2300  $\mu\text{g g}^{-1}$  dw; Zn: range 20-35  $\mu\text{g g}^{-1}$  dw; [Finger et al., 2016](#); [Lucia et al., 2016](#); [Sebastiano et al., 2017, 2016](#), but see [Carvalho et al., 2013](#); [Osborn et al., 1979](#)), suggesting that they are maintained in a narrow range of concentrations as a consequence of homeostatic processes. White-chinned and snow petrels had higher Mn concentrations than those of other seabirds (adults, [Anderson et al., 2010](#); [Finger et al., 2016](#)). Most penguin species had Se concentrations in the range of other seabird chicks ( $<10 \mu\text{g g}^{-1}$  dw, [Burger and Gochfeld, 1997](#); [Sebastiano et al., 2016](#)), while petrels and albatrosses had higher burdens (10-60  $\mu\text{g g}^{-1}$  dw). Surprisingly, macaroni penguin chicks had very high Se concentrations, similar to those of adults of some procellariiformes species (100-200  $\mu\text{g g}^{-1}$  dw, [Anderson et al., 2010](#); [González-Solís et al., 2002](#)), but lower than those of brown skua chicks from Amsterdam Island (up to 650  $\mu\text{g g}^{-1}$  dw on average, highest burden reported so far in wild bird chicks, [Carravieri et al., 2017](#)). This could stem from concurring trophic and physiological factors that are discussed below (Section 2.1).

Only a handful of studies have reported blood POPs concentrations in seabird chicks worldwide ([Bourgeon et al., 2013](#); [Carravieri et al., 2017](#); [Colabuono et al., 2016](#); [Sebastiano et al., 2017, 2016](#)), because low concentrations and a limitation in the volume of blood that can be sampled, complicate POPs quantification in this age class. Chicks from the present study had overall low burdens of POPs, in particular PCBs but also most organochlorine pesticides (chlordanes, Mirex, DDT metabolites), which were detected in a very few individuals. As expected, the only exception to this general pattern was HCB, a POP known to strongly bioaccumulate and biomagnify in Southern Ocean food webs ([Bengtson Nash et al., 2007](#)). HCB was detected in almost all individuals at concentrations i) comparable to other Southern Hemisphere seabird chicks ([Carravieri et al., 2017](#); [Colabuono et al., 2016](#)), and ii) higher than those of Northern Hemisphere species ([Bourgeon et al., 2013](#); [Sebastiano et al., 2017, 2016](#)). Blood POPs concentrations in adults of other Antarctic and subantarctic species were overall

higher than those found in chicks of the present study (Corsolini et al., 2007; Dehnhard et al., 2017; Tartu et al., 2015), likely as a consequence of exposure of the adults during longer periods over distant wintering areas (Weimerskirch et al. 2015).

#### *4.2. Intrinsic and extrinsic drivers of contaminant concentrations*

##### *4.2.1. Hg and Se*

Since Hg is efficiently biomagnified under its methylated form (Me-Hg), high trophic level prey, such as fish and cephalopods show higher Hg concentrations than planktonic organisms (Anderson et al., 2009; Lavoie et al., 2013). Hence, inter-specific variability in seabird Hg exposure is often attributed to their trophic level (Anderson et al., 2009; Blévin et al., 2013). Yet in the present study, spatial factors seemed to overcome trophic drivers to a certain extent. As previously shown at the individual (Carravieri et al., 2014b), population (Carravieri et al., 2017), species (Cherel et al., 2018) and community levels (Blévin et al., 2013; Carravieri et al., 2014c), inter-specific differences in Hg concentrations in blood were strongly driven by feeding habitat ( $\delta^{13}\text{C}$  values). Specifically, all chicks fed with Antarctic prey, from both neritic (emperor and Adélie penguins) and oceanic waters (small petrels), had low blood Hg concentrations irrespective of their trophic position, at both the inter- and intra-specific scale. This confirms the homogeneity of Hg transfer to upper predators in waters south of the Polar Front (Carravieri et al., 2017, 2014b; Cherel et al., 2018), in both neritic and oceanic environments. High Me-Hg concentrations in Antarctic coastal waters, particularly in association with sea-ice (Cossa et al., 2011), and relatively high Hg burdens in key prey species such as Antarctic krill *Euphausia superba* (Seco et al., 2019) contrast with low Hg concentrations in Antarctic upper predators. This suggests that the relative simplicity of Antarctic food webs, where upper predators rely on a few key mid-trophic species, prevents strong biomagnification of Hg in Antarctic waters.

There was a net increase in blood Hg concentrations in species feeding north of the Polar Front (Fig. 3, Cherel et al., 2018), since most chicks at the subantarctic Crozet Islands displayed relatively high Hg concentrations. At the subtropical site, the micronekton-eater northern rockhopper penguin had 3- and 12-fold lower blood Hg concentrations than yellow-nosed and Amsterdam albatrosses, respectively, which rely on high trophic level prey (Cherel et al., 2013). Yet, northern rockhopper penguin Hg concentrations were similar to those of southern rockhopper penguins at Crozet archipelago, suggesting comparable Hg content in subtropical and subantarctic micronektonic species. In addition, the within-population slopes of the relationship between blood Hg and  $\delta^{13}\text{C}$  values were weak in Antarctic waters, and progressively steeper from subantarctic to subtropical environments (Fig. 3), emphasising a strong Hg transfer variation in different water masses. Contrary to findings at Kerguelen Islands (Carravieri et al., 2013), gentoo penguins feeding on pelagic prey (low  $\delta^{13}\text{C}$  values) had higher blood Hg concentrations than benthic feeders (high  $\delta^{13}\text{C}$  values). This could be related to the birds' trophic positions, because  $\delta^{15}\text{N}$  values were exceptionally high in those individuals with low  $\delta^{13}\text{C}$  values (Fig. S3). Collectively, our results indicate a stronger biomagnification of Hg in subtropical than subantarctic and Antarctic waters. This inversed latitudinal pattern in Hg biomagnification strength contradicts previous large-scale results in aquatic food webs (Lavoie et al., 2013). A broad quantification of Hg concentrations and its chemical forms in seabirds' prey over a large latitudinal range is necessary to clarify this pattern.

Hg dynamics in organisms can also be influenced by Se. Specifically, at high concentrations Hg and Se are known to interact and mitigate mutually their toxic effects (Cuvillier-Vacher and Furness, 1991). Hg and Se concentrations often correlate in seabird tissues, and the Se:Hg ratio is used as an indicator of the balance between the two elements, and thus to infer potential risk of toxicity (Scheuhammer et al., 2015). Se concentrations did not show obvious geographical patterns, and were not correlated to Hg burdens. Yet, between-species differences

were substantial. Specifically, blue petrels and thin-billed prions had high blood Se concentrations, likely as a result of feeding on Se-rich crustacean species such as *T. gaudichaudii* (Anderson et al., 2010). Macaroni penguin chicks are also fed extensively with crustaceans, in particular the euphausiid *Euphausia vallentini* and *T. gaudichaudii* (Ridoux, 1994; Cherel et al., 2007), being likely exposed to large quantities of dietary Se. Yet, such a strikingly high Se concentrations in blood compared to the other crustacean-consumers could also be the result of specific physiological mechanisms that need further investigation. Hg concentrations in macaroni penguin chick feathers (authors' unpublished data) were unexpectedly low given their Hg burdens in blood. Indeed, their feather to blood ratio was 0.5, while it was in the range 1.7-6.1 in all other species. This could suggest that macaroni penguin chicks have a reduced capacity of Hg excretion into feathers that might be compensated by an increased, selective absorption and accumulation of Se from the diet, in order to achieve protection against Hg toxicity.

#### 4.2.2. Other trace elements

Even though variation in essential trace elements was lower than in non-essential ones, clear differences were highlighted among species. Chick body mass was shown to be a significant predictor of essential element concentrations, in particular of Zn. These results are consistent with optimal concentrations of essential elements being species-specific (Walker et al., 2012). The clear decrease of Zn concentrations with body mass was unexpected and could suggest either that i) smaller species have higher requirements of Zn, or ii) Zn requirements are similar across species, but circulating concentrations are subject to a dilution effect, or other body mass-dependent physiological mechanisms. Feeding habitat ( $\delta^{13}\text{C}$  values) also explained partially the variation in essential trace element concentrations. Blood Cu and Fe concentrations were high in neritic species such as Adélie and gentoo penguins, suggesting high bioavailability

of these elements in association with shelves. Conversely, blood Cu concentrations were low in chicks fed with pelagic prey from Antarctic waters, which is consistent with low essential element concentrations in Southern Ocean waters (Petri and Zauke, 1993). Finally, by considering results in the 13 species, and comparison with the literature (see Section 4.1 above), yellow-nosed and Amsterdam albatross chicks seem to be Fe-deficient, although the rationale is unclear. Certainly there is a need for a better understanding of the factors that govern essentiality ranges in wild birds.

#### 4.2.3. POPs

Contrary to previous studies (Carravieri et al., 2014b; Roscales et al., 2016), here there was no clear geographical pattern in blood POPs concentrations in seabird chicks. Instead, chicks fed with prey captured in open oceanic waters had higher concentrations than those relying on neritic prey, irrespective of the water mass. Specifically, blue petrels and thin-billed prions, which feed on small crustaceans captured at the surface in high-productivity Antarctic oceanic waters (Cherel et al., 2014), had the most varied patterns (HCB but also 4,4'-DDE, heptachlor and trans-nonachlor) and higher POPs concentrations of all species. This is consistent with results in tissues of Antarctic prions *Pachiptyla desolata*, which showed a remarkable diversity of organic compounds (Fromant et al., 2016). Conversely, northern rockhopper penguins, which feed on micronekton in subtropical waters, had the lowest abundance of POPs in blood. This suggests that feeding on low trophic level prey from surface, productive Antarctic oceanic waters lead to high exposure from ready integration of POPs into food webs (biological pump, Galbán-Malagón et al., 2012). Amsterdam albatross chicks had similarly high and diverse POP burdens (HCB but also 2,4'-DDE, 4,4'-DDE, 4,4'-DDT, heptachlor and trans-nonachlor), likely as a result of feeding at a very high trophic level. Quantification of POPs burdens in seabirds' prey from Antarctic, to subantarctic, up to

subtropical waters is necessary to give a better picture of the spatial *versus* trophic factors that drive transfer of POPs to seabirds.

#### *4.3. Species that raise ecotoxicological concern*

Strong evidence from laboratory and fieldwork studies indicates that non-essential elements such as Cd, Hg, and Pb, and POPs have several deleterious effects on seabird physiology ([Eagles-Smith et al., 2018](#)). Specifically, they can disrupt key neurological and endocrine mechanisms, with consequences on development, reproduction, and survival ([Goutte et al., 2018](#); [Tan et al., 2009](#); [Tartu et al., 2015](#)). These contaminants can also cause immunosuppression; they increase susceptibility to disease, the abundance of intestinal parasitic nematodes, and can alter the immune response ([Letcher et al., 2010](#); [Sagerup et al., 2000](#)). On the other hand, concentrations of essential elements that fall outside the window of essentiality can also have negative impacts (deficiency/toxicity, [Walker et al., 2012](#)). Here, Amsterdam albatross chicks (i) had high burdens of Hg (see also [Cherel et al. 2018](#)) and HCB, (ii) were recently exposed to DDT (contrary to most other species), and (iii) had relatively low concentrations of essential elements such as Fe, Se, and Zn, which are critical for blood production (Fe), protection against Hg toxicity and oxidative stress (Se), and immunity and growth (Zn) ([Smith, 2003](#); [Walker et al., 2012](#)). A very similar pattern of contamination was found in yellow-nosed albatross chicks, although Hg concentrations were not as high. These results raise toxicological concern for these two endangered species, in particular in relation to outbreaks of avian cholera, which impacts the yellow-nosed albatross population with demographic consequences ([Rolland et al., 2009](#); [Weimerskirch, 2004](#)). Although POPs concentrations were overall low relative to other seabirds worldwide, the diversity and concentrations found in small petrel species using surface-feeding strategies deserves further investigation, also in relation to their vulnerability to plastic debris ingestion ([Fromant et al.,](#)

2016). Finally, the extremely high Se:Hg molar ratios in macaroni penguins and small petrels (~300-1800) indicate a disproportional excess of Se over Hg, with potential toxicological consequences.

## 5. Conclusion

This work is a significant contribution to our understanding of contaminant exposure and accumulation in seabirds from remote sites of the Southern Hemisphere. A key finding was the large variation in contaminant concentrations among species, including of some essential trace elements, as a result of a combination of intrinsic (species, body mass) and extrinsic (diet and habitat) drivers. Hg transfer to seabirds was confirmed to increase from Antarctic to subtropical latitudes, while POP transfer seemed to be stronger to small pelagic petrels feeding in subantarctic and Antarctic waters. Yet, quantification of Hg and POP burdens in prey species from Antarctic, to subantarctic, up to subtropical waters is necessary to give a better picture of the spatial *versus* trophic factors that drive transfer to seabirds. Our results raise toxicological concern for Amsterdam and yellow-nosed albatrosses, as well as small petrel species and macaroni penguins, which should be further investigated. In order to fully quantify exposure risk at populations' and species' level, contaminant concentrations should be measured in adults too, over both the breeding and non-breeding period. Representative species with contrasted feeding strategies that could be used as bioindicators for long-term monitoring, in addition to those previously identified (Blévin et al., 2013; Carravieri et al., 2014c, 2013), are emperor penguins and snow petrels in Antarctica, and northern rockhopper penguins and yellow-nosed albatrosses in the subtropics.

## Declaration of Competing Interest

The authors declare that there are no conflicts of interest.

**Acknowledgements:** This work was supported financially and logistically by the Région Poitou-Charentes through a PhD grant to A.C., and by the Agence Nationale de la Recherche (program POLARTOP, O. Chastel), the Institut Polaire Français Paul Emile Victor (IPEV, program no. 109, H. Weimerskirch) and the Terres Australes et Antarctiques Françaises (TAAF). Field procedures were authorised by the Ethics Committee of IPEV and by the Comité de l'Environnement Polaire. The authors thank all the numerous fieldworkers who helped collecting blood samples from chicks over the four sites. The Aquitaine Region and the European Union (CPER A2E project) are also acknowledged for their financial support. Europe is moving in Aquitaine with the European Regional Development Fund. The IUF (Institut Universitaire de France) is acknowledged for its support to P.B. as a Senior Member. The authors are grateful to M. Brault-Favrou and C. Churlaud from the Plateforme Analyses Élémentaires and to G. Guillou from the Plateforme Analyses Isotopiques of the LIENSs laboratory, for running trace element and stable isotope analysis, and to L. Peluhet from EPOC-LPTC for carrying out POPs quantification. The authors thank three anonymous reviewers who strongly improved the manuscript.

Factor <sup>a</sup>			3	1.4	53	57	132	1.5	15

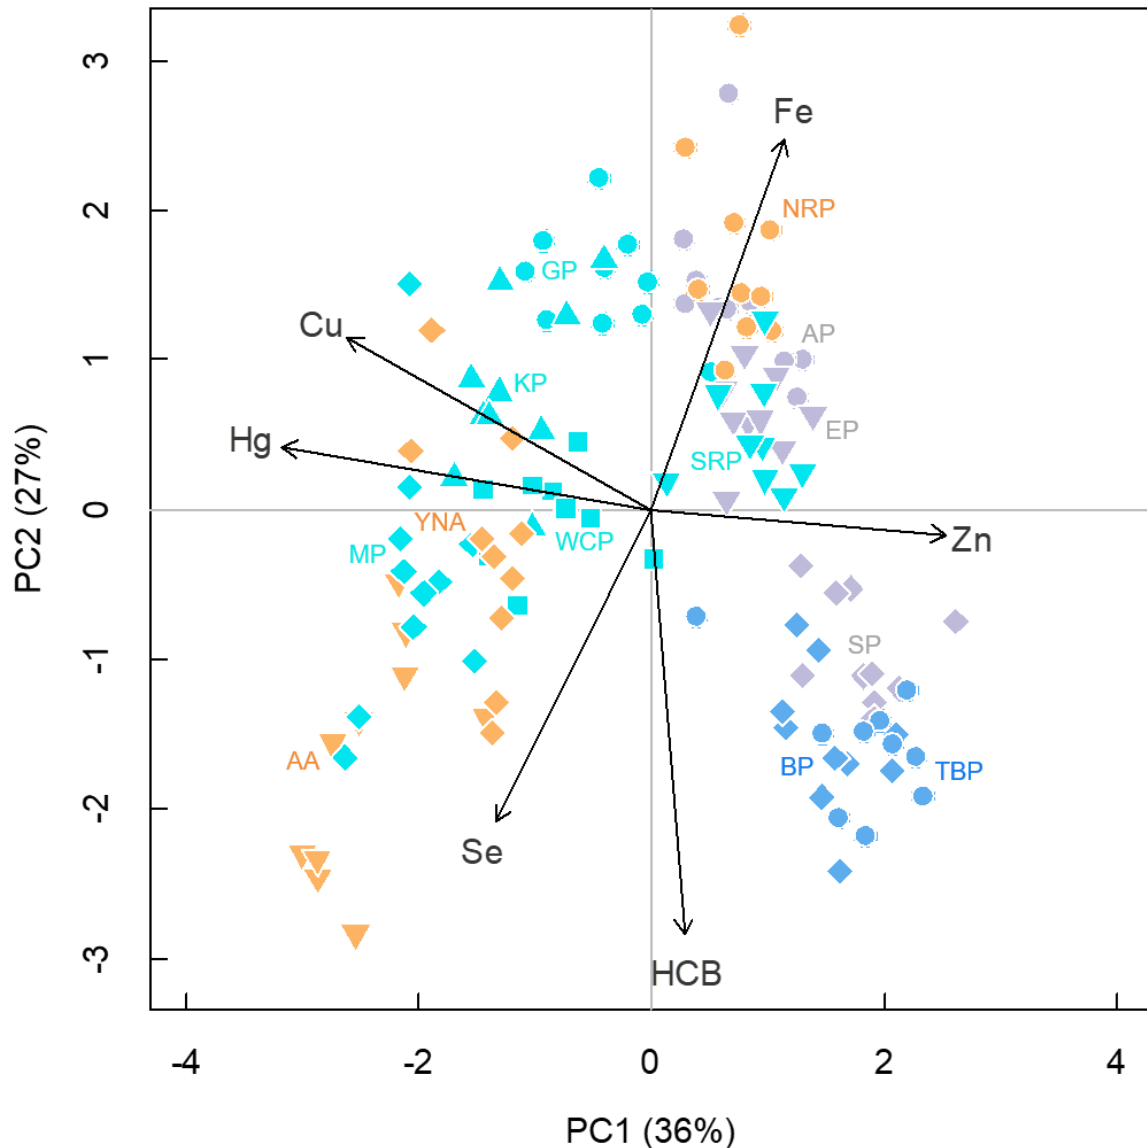

\* N=10 for HCB determination

\*\* N=11 for HCB determination

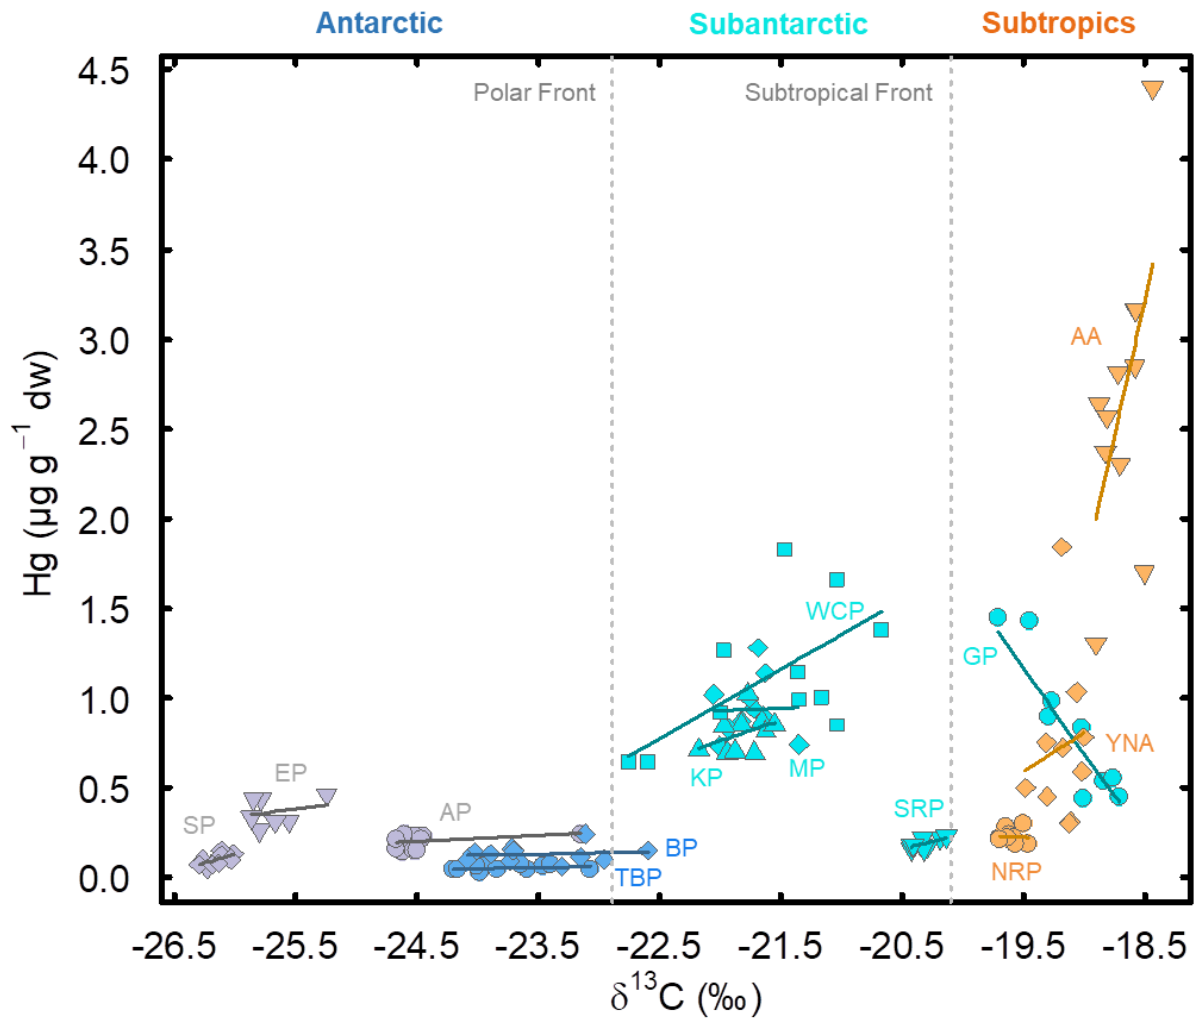

<sup>a</sup> Factor between the species with the highest and lowest mean concentrations of all contaminants and the Se:Hg ratio.

**Figure 1.** Standard ellipse areas corrected for small sample size of red blood cell  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  (‰) values in chicks of penguins, petrels and albatrosses from the southern Indian Ocean. Abbreviations: AA, Amsterdam albatrosses; AP, Adélie penguins; BP, blue petrels; EP, emperor penguins; GP, gentoo penguins; KP, king penguins; MP, macaroni penguins; NRP, northern rockhopper penguins; SP, snow petrels; SRP, southern rockhopper penguins; TBP, thin-billed prions; WCP, white-chinned petrels; YNA, Indian yellow-nosed albatrosses.

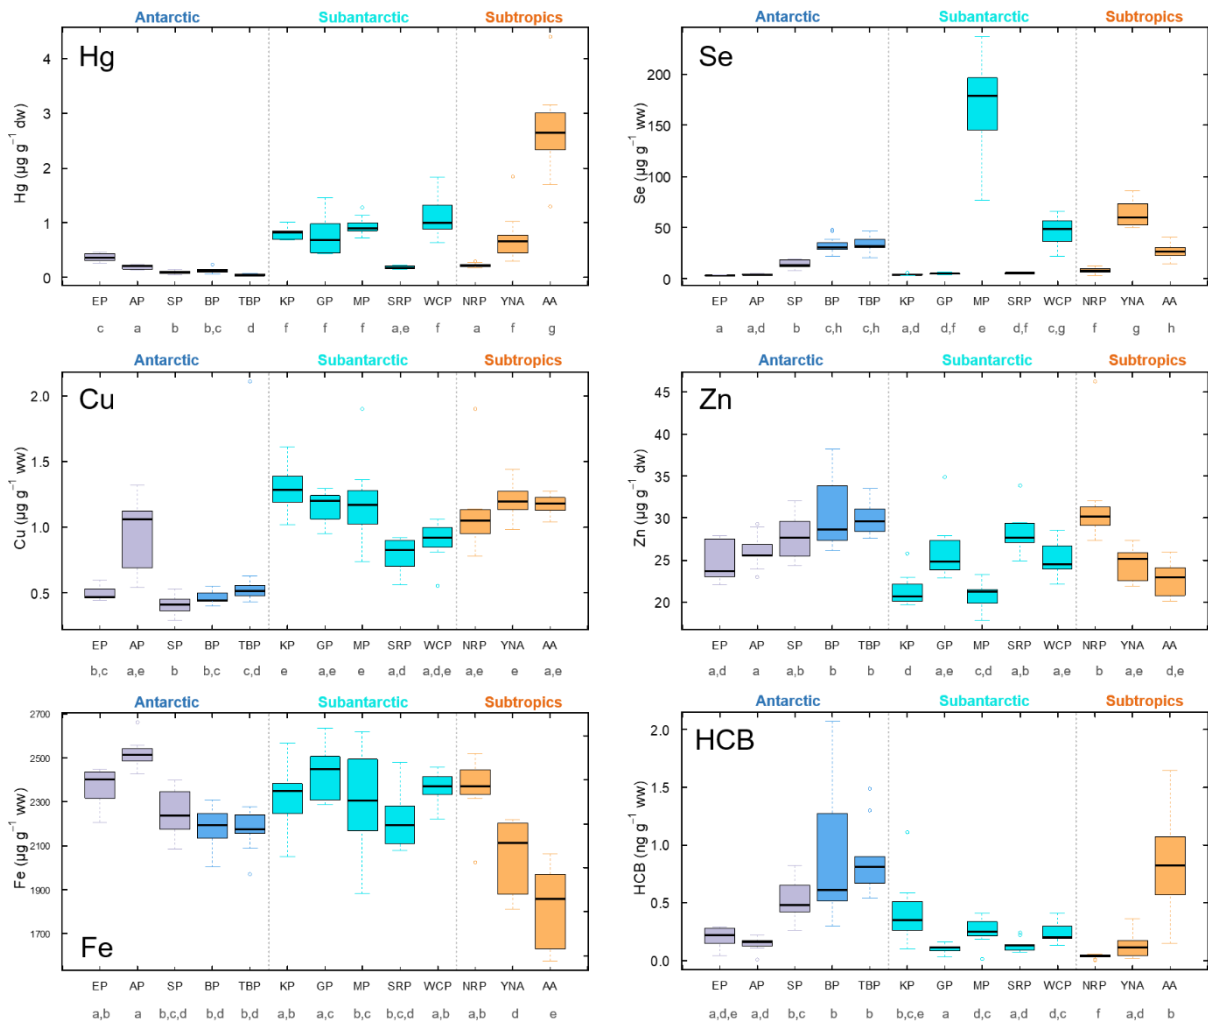

**Figure 2.** Biplot of individual scores and element loadings on the two principal axes (PC1 and PC2), obtained from a principal component analyses (PCA) on standardised red blood cell trace elements and plasma HCB concentrations in chicks of penguins, albatrosses and petrels from the southern Indian Ocean. Colour legend: grey: high Antarctic zone; dark blue: Antarctic zone; light blue: subantarctic zone; orange: subtropical zone. Abbreviations: AA, Amsterdam albatrosses; AP, Adélie penguins; BP, blue petrels; EP, emperor penguins; GP, gentoo penguins; KP, king penguins; MP, macaroni penguins; NRP, northern rockhopper penguins; SP, snow petrels; SRP, southern rockhopper penguins; TBP, thin-billed prions; WCP, white-chinned petrels; YNA, Indian yellow-nosed albatrosses.

**Figure 3.** Relationship between red blood cell Hg concentrations ( $\mu\text{g g}^{-1} \text{ dw}$ ) and  $\delta^{13}\text{C}$  (‰) values in chicks of penguins, albatrosses and petrels from the southern Indian Ocean. Fitted lines represent the best selected model ( $\text{Hg} \sim \text{species} + \delta^{13}\text{C} + \text{species}:\delta^{13}\text{C}$ , Table 3). Vertical lines delimitate the water masses (Antarctic, subantarctic, subtropics) where parents capture prey for their chicks according to stable isotope results (Fig. S1) and previous work on the same populations (Table S1). Abbreviations: AA, Amsterdam albatrosses; AP, Adélie penguins; BP, blue petrels; EP, emperor penguins; GP, gentoo penguins; KP, king penguins; MP, macaroni penguins; NRP, northern rockhopper penguins; SP, snow petrels; SRP, southern rockhopper penguins; TBP, thin-billed prions; WCP, white-chinned petrels; YNA, Indian yellow-nosed albatrosses.

**Figure 4.** Concentrations of Hg, Cu, Fe, Se, and Zn ( $\mu\text{g g}^{-1}$  dw) in red blood cells and HCB ( $\text{ng g}^{-1}$  ww) in plasma of chicks of penguins, albatrosses and petrels from the southern Indian Ocean. Species order representation is based on latitude of feeding grounds where parents capture prey for their chicks, and their trophic positions, according to stable isotope results (Fig. 1) and previous work on the same populations (Table S1). Vertical lines delimitate the southern Indian Ocean water masses (Antarctic, subantarctic, subtropics). Letters indicate significant between-species differences (Tukey HSD,  $p < 0.05$ ). Abbreviations: AA, Amsterdam albatrosses; AP, Adélie penguins; BP, blue petrels; EP, emperor penguins; GP, gentoo penguins; KP, king penguins; MP, macaroni penguins; NRP, northern rockhopper penguins; SP, snow petrels; SRP, southern rockhopper penguins; TBP, thin-billed prions; WCP, white-chinned petrels; YNA, Indian yellow-nosed albatrosses.

## 1. Quality assurance and quality control for trace element and persistent organic pollutant quantification

### 1.1 Mercury

Total mercury (Hg) was quantified with an Altec AMA 254 spectrophotometer on aliquots of 1-10 mg dry weight (dw) as described in [Bustamante et al. \(2006\)](#). All analyses were repeated in duplicate-triplicate until having a relative standard deviation (SD) < 10% for each individual. Accuracy was checked using a certified reference material (CRM, TORT-2 Lobster Hepatopancreas, NRC, Canada; certified Hg concentration:  $0.27 \pm 0.06 \mu\text{g g}^{-1} \text{ dw}$ ). Our measured values were  $0.27 \pm 0.01 \mu\text{g g}^{-1} \text{ dw}$ ,  $N = 44$ . Mass of the CRM was adjusted to represent an amount of Hg similar to that in blood samples. Blanks were analysed at the beginning of each set of samples and the limit of detection (LOD) was  $0.005 \mu\text{g g}^{-1} \text{ dw}$ .

### 1.2 Essential and non-essential trace elements

Arsenic (As), chromium (Cr), copper (Cu), iron (Fe), manganese (Mn), nickel (Ni), selenium (Se) and zinc (Zn) were analysed using a Varian Vista-Pro ICP-OES and silver (Ag), cadmium (Cd), cobalt (Co), lead (Pb) and vanadium (V) using a Thermo Fisher Scientific X Series 2 ICP-MS, following [Kojadinovic et al. \(2011\)](#) (aliquots mass: 20-200 mg dw). Measurement quality was assessed by CRM (TORT-2 Lobster Hepatopancreas and DOLT-4 Dogfish Liver, both NRC, Canada). Elements' recoveries were (% , mean  $\pm$  SD)  $83 \pm 1$  (Ag),  $99 \pm 9$  (As),  $96 \pm 2$  (Cd),  $101 \pm 2$  (Co),  $74 \pm 4$  (Cr),  $98 \pm 3$  (Cu),  $97 \pm 6$  (Fe),  $93 \pm 1$  (Mn),  $96 \pm 13$  (Ni),  $83 \pm 9$  (Pb),  $104 \pm 6$  (Se),  $93 \pm 11$  (V), and  $104 \pm 2$  (Zn). Blanks were included in each analytical batch. Element-specific LODs are reported in [Table S2](#).

### 1.3 Persistent organic pollutants

The targeted compounds were seven PCBs (CB-28, -52, -101, -118, -138, -153 and -180) and 11 OCPs (HCB,  $\gamma$ -HCH, Heptachlor, 2,4'-DDE, 4,4'-DDE, *cis*-chlordane, *trans*-

nonachlor, 4,4'-DDD, 2,4'-DDT, 4,4'-DDT, Mirex). The targeted CB-28 co-eluted with CB-50 in all samples and is thus reported as CB-28/50. Internal standards (CB-30, -103, -155, -198 and p,p'-DDT-d8, 1 ng each) were added to each sample. Standards were provided by either Dr Ehrenstorfer GmbH or Cambridge Isotope Laboratory (via Cluzeau Info Labo, Sainte-Foy-La-Grande, France). Sample extraction, purification and concentration followed the procedure described in Carravieri et al. (2014). Replicate procedural blanks were analysed for each series of samples and, when applicable, POP concentrations were blank-corrected. Final extracts were analysed by gas chromatography coupled with electron capture detection (GC-ECD) as described in Tapie et al. (2011). Recovery rates, as determined on spiked chicken plasma, were  $92 \pm 6$  (CB-28/50),  $81 \pm 13$  (CB-52),  $91 \pm 12$  (CB-101),  $105 \pm 6$  (CB-118),  $100 \pm 5$  (CB-153),  $102 \pm 3$  (CB-138),  $105 \pm 3$  (CB-180),  $65 \pm 6$  (HCB),  $70 \pm 6$  ( $\gamma$ -HCH),  $50 \pm 5$  (Heptachlor),  $80 \pm 4$  (*cis*-chlordane),  $83 \pm 4$  (*trans*-nonachlor),  $81 \pm 4$  (2,4'-DDE),  $90 \pm 2$  (4,4'-DDE),  $95 \pm 3$  (4,4'-DDD),  $85 \pm 4$  (2,4'-DDT),  $92 \pm 3$  (4,4'-DDT), and  $60 \pm 20$  (Mirex). POP-specific limits of quantification (LOQs) are reported in Table S3.

**Table S1.** International Union for the Conservation of Nature (IUCN, 2019) status of 13 species of penguins, albatrosses and petrels and their foraging ecology during the chick-rearing period in the southern Indian Ocean.

Species (abbreviation)	Scientific name	IUCN status	Adult feeding habitat during chick rearing			Main chick prey	References
			Oceanic zone	Horizontal	Vertical		
<b>Adélie Land, Antarctica</b>							
Emperor penguin (EP)	<i>Aptenodytes forsteri</i>	Near Threatened	Antarctic	Neritic	Pelagic	Fish	Cherel, 2008; Offredo and Ridoux, 1986; Zimmer et al., 2008
Adélie penguin (AP)	<i>Pygoscelis adeliae</i>	Least Concern	Antarctic	Neritic	Pelagic	Crustaceans (fish)	Cherel, 2008; Ridoux and Offredo, 1989; Widmann et al., 2015; Wienecke et al., 2000
Snow petrel (SP)	<i>Pagodroma nivea</i>	Least Concern	Antarctic	Neritic	Sea surface	Fish (crustaceans)	Delord et al., 2016; Ridoux and Offredo, 1989
<b>Mayès Island, Kerguelen archipelago</b>							
Blue petrel (BP)	<i>Halobaena caerulea</i>	Least Concern	Subantarctic, Antarctic	Oceanic	Sea surface	Crustaceans (mesopelagic fish)	Bocher et al., 2001; Cherel et al., 2002b, 2014; Connan et al., 2007, 2008
Thin-billed prion (TBP)	<i>Pachyptila belcheri</i>	Least Concern	Subantarctic, Antarctic	Oceanic (neritic)	Sea surface	Crustaceans	Bocher et al., 2001; Cherel et al., 2014, 2002a; Connan et al., 2007
<b>Possession Island, Crozet archipelago</b>							
King penguin (KP)	<i>Aptenodytes patagonicus</i>	Least Concern	Subantarctic, Polar front	Oceanic	Pelagic	Mesopelagic fish	Cherel et al., 2007, 1993; Cherel and Ridoux, 1992; Ridoux, 1994; Bost et al., 1997
Gentoo penguin (GP)	<i>Pygoscelis papua</i>	Least Concern	Subantarctic	Neritic	Benthic, pelagic	Crustaceans (fish)	Bost et al., 1994; Ridoux, 1994
Macaroni penguin (MP)	<i>Eudyptes chrysolophus</i>	Vulnerable	Subantarctic	Oceanic	Pelagic	Crustaceans (fish)	Bon et al., 2015; Cherel et al., 2007; Ridoux, 1994
Southern rockhopper penguin (SRP)	<i>Eudyptes chrysocome</i>	Vulnerable	Subantarctic	Oceanic (neritic)	Pelagic	Crustaceans	Cherel et al., 2007; Ridoux, 1994; Tremblay and Cherel, 2003
White-chinned petrel (WCP)	<i>Procellaria aequinoctialis</i>	Vulnerable	Subantarctic, Antarctic	Oceanic	Sea surface	Fish (cephalopods, crustaceans)	Catard et al., 2000; Connan et al., 2007; Ridoux, 1994
<b>Amsterdam Island</b>							
Northern rockhopper p. (NRP)	<i>Eudyptes moseleyi</i>	Endangered	Subtropics (Amsterdam waters)	Oceanic	Pelagic	Fish, crustaceans, squid	Cherel et al., 1999; Tremblay et al., 1997; Tremblay and Cherel, 2003
Indian yellow-nosed al. (YNA)	<i>Thalassarche carteri</i>	Endangered	Subtropics	Oceanic	Sea surface	Fish (cephalopods)	Cherel et al., 2013; Pinaud et al., 2005
Amsterdam albatross (AA)	<i>Diomedea amsterdamensis</i>	Endangered	Subtropics	Oceanic	Sea surface	Unknown	Cherel et al., 2013; Thiebot et al., 2014

**Table S2.** Concentrations ( $\mu\text{g g}^{-1}$  dw), limit of detection (LOD,  $\mu\text{g g}^{-1}$  dw), and detection frequency (DF, %) of trace elements in red blood cells of chicks of penguins, albatrosses and petrels from the southern Indian Ocean. Total and quantifiable sample sizes are given in parenthesis next to species names and element values, respectively. Values are mean  $\pm$  SD in the first line, and median and (range) in the second one.

Null	1	10	140	0.00	0.00

<sup>a</sup> Number of parameters.

<sup>b</sup> Scaled AICc; AICc = 0.00 is interpreted as the best fit to the data among the models.

<sup>c</sup> Weight of evidence interpreted as a proportion. Weights across all models sum to 1.00.

<sup>d</sup> Explained deviance adjusted by  $k$  and  $N$ .

**Table S6.** Sum of Akaike’s weights across all models of each tested explanatory variable of red blood cell trace element and plasma HCB concentrations in chicks of penguins, albatrosses and petrels from the southern Indian Ocean.

Variables	Sum of Akaike’s weights across all models					
	<b>Cu</b>	<b>Fe</b>	<b>Hg</b>	<b>Se</b>	<b>Zn</b>	<b>HCB</b>
