Abstract. The stable sedimentary nitrogen isotope compositions of bulk organic matter ($\delta^{15}\text{N}_{\text{bulk}}$) and the silicon isotope composition of diatoms ($\delta^{30}\text{Si}_{\text{BSi}}$) both mainly reflect the degree of past nutrient utilization by primary producers. However, in ocean areas where anoxic and suboxic conditions prevail, the $\delta^{15}\text{N}_{\text{bulk}}$ signal ultimately recorded within the sediments is also influenced by water column denitrification, causing an increase in the subsurface $\delta^{15}\text{N}$ signature of dissolved nitrate ($\delta^{15}\text{NO}_3^-$) upwelled to the surface. Such conditions are found in the oxygen minimum zone off the coast of Peru, where, at present, an increase in subsurface $\delta^{15}\text{NO}_3^-$ from north to south along the shelf is observed due to ongoing denitrification within the poleward-flowing subsurface waters, while the $\delta^{30}\text{Si}$ signature of silicic acid ($\delta^{30}\text{Si}(\text{OH})_4$) at the same time remains unchanged.

Here, we present three new $\delta^{30}\text{Si}_{\text{BSi}}$ records between 11 and 15° S and compare these to previously published $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ records from Peru covering the past 600 years. We present a new approach to calculate past subsurface $\delta^{15}\text{NO}_3^-$ signatures based on the direct comparison of $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures at a latitudinal resolution for different time periods. Our results show that, during the Current Warm Period (CWP, since 1800 CE) and prior short-term arid events, source water $\delta^{15}\text{NO}_3^-$ compositions have been close to modern values, increasing southward from 7 to 10‰ (between 11 and 15° S). In contrast, during the Little

Ice Age (LIA) we calculate low $\delta^{15}\text{NO}_3^-$ values between 6‰ and 7.5‰. Furthermore, the direct $\delta^{30}\text{Si}_{\text{BSi}}$ versus $\delta^{15}\text{N}_{\text{bulk}}$ comparison also enables us to relate the short-term variability in both isotope compositions to changes in the ratio of nutrients ($\text{NO}_3^- : \text{Si}(\text{OH})_4$) taken up by different dominating phytoplankton groups (diatoms and non-siliceous phytoplankton) under the variable climatic conditions of the past 600 years. Accordingly, we estimate a shift from a 1 : 1 (or 1 : 2) ratio during the CWP and a 2 : 1 (up to 15 : 1) ratio during the LIA, associated with a shift from overall high nutrient utilization to NO_3^- -dominated (and thus non-siliceous phytoplankton) utilization.

1 Introduction

Investigations of the isotopic compositions of the macronutrients, such as silicic acid ($\text{Si}(\text{OH})_4$) and nitrate (NO_3^-), have been used to infer changes of biogeochemical cycles in the past (Brunelle et al., 2007; Horn et al., 2011; Robinson et al., 2014). The preferential incorporation of the lighter isotopes ^{14}N and ^{28}Si into organic matter (OM) and biogenic opal (BSi), respectively, during primary production in surface waters leads to an increase in the $\delta^{15}\text{N}$ and $\delta^{30}\text{Si}$ in the remaining dissolved nutrients (i.e., $\delta^{15}\text{NO}_3^-$ and $\delta^{30}\text{Si}(\text{OH})_4$), as a result of progressive consumption of the

nutrient pools (Altabet et al., 1991; De La Rocha et al., 1997; Wada and Hattori, 1978). This preferential incorporation is associated with an approximate enrichment factor of -5‰ for NO_3^- (Waser et al., 1998) and -1.1‰ for $\text{Si}(\text{OH})_4$ (De La Rocha et al., 1997), which agree well with estimates for the Peruvian shelf (Ehlert et al., 2012; Mollier-Vogel et al., 2012; Grasse et al., 2016). While a potential fractionation of $\delta^{30}\text{Si}$ signatures of biogenic opal during dissolution of -0.55‰ has been reported previously (Demarest, 2009), investigations from the water column of the Southern Ocean did not find significant difference between the $\delta^{30}\text{Si}$ values of particles in the water column and in surface sediments (Varela et al., 2004; Fripiat et al., 2012; Closset et al., 2015). Furthermore, field studies and laboratory experiments based on sediments have so far indicated that $\delta^{30}\text{Si}$ signatures of diatoms within the sediments are generally unaffected by diagenetic alteration (e.g., Egan et al., 2012; Wetzel et al., 2014; Ehlert et al., 2016). Accordingly, the degree of utilization of NO_3^- and $\text{Si}(\text{OH})_4$ is recorded in the $\delta^{15}\text{N}_{\text{bulk}}$ and $\delta^{30}\text{Si}_{\text{BSi}}$ of the organic matter (OM) and BSi produced. In combination with parameters such as organic carbon, BSi or barium accumulation rates, both $\delta^{15}\text{N}_{\text{bulk}}$ and $\delta^{30}\text{Si}_{\text{BSi}}$ have been employed as proxies for the evaluation of past productivity and corresponding nutrient utilization (De La Rocha et al., 1998; François et al., 1992; Horn et al., 2011; Pichevin et al., 2005).

However, in coastal upwelling areas, where upwelling of nutrient-rich subsurface waters causes high surface productivity, subsequent degradation of the high amounts of OM leads to extensive oxygen consumption in the water column (Pennington et al., 2006; Zuta and Guillén, 1970). As a result of the low oxygen concentrations, NO_3^- is used as an oxidant during OM degradation and is transferred to N_2 , leading to a net loss of bioavailable nitrogen, e.g., denitrification and anaerobic ammonium oxidation (Codispoti, 2007; Lam et al., 2009). Due to the high isotope fractionation factor ($\sim -20\text{‰}$) associated with denitrification, the $\delta^{15}\text{NO}_3^-$ signatures of subsurface waters strongly increase and consequently supply a heavy $\delta^{15}\text{NO}_3^-$ signal to surface waters during upwelling (Cline and Kaplan, 1975). This ^{15}N -enriched NO_3^- is incorporated by phytoplankton and ultimately deposited and buried in marine sediments. Accordingly, although $\delta^{15}\text{N}_{\text{bulk}}$ also varied in phase with productivity proxies, elevated $\delta^{15}\text{N}_{\text{bulk}}$ values in highly productive and poorly ventilated regions, including most of the coastal upwelling areas, have been generally interpreted as the consequence of stronger denitrification associated with intense oxygen depletion (Agnihotri et al., 2006, 2008; De Pol-Holz et al., 2007; Fleury et al., 2015; Gutiérrez et al., 2009; Mollier-Vogel et al., 2012; Salvatelli et al., 2014b). However, given that dissolved $\delta^{15}\text{NO}_3^-$ is influenced by both nutrient utilization and denitrification – associated with water column deoxygenation – both processes should also influence the $\delta^{15}\text{N}_{\text{bulk}}$ signatures recorded by the sedimentary OM.

In contrast, $\delta^{30}\text{Si}_{\text{BSi}}$ signatures are primarily controlled by surface water diatom productivity and $\text{Si}(\text{OH})_4$ utilization

(Brzezinski, 2002; De La Rocha et al., 1998), closely coupled to the amount of upwelling strength in the study area (Doering et al., 2016; Ehlert et al., 2013, 2015, 2012; Grasse et al., 2013). Accordingly, downcore records of $\delta^{30}\text{Si}_{\text{BSi}}$ off the coast of Peru are closely coupled to changes in the diatom assemblage, with high signatures ($>1\text{‰}$) reflecting strong upwelling conditions and lower signatures (0.5‰ – 1‰) reflecting weak upwelling conditions (Doering et al., 2016). This coupling was previously shown to be mainly the consequence of changes in the relative abundance of different diatom groups during diatom succession linked to different upwelling strength (Doering et al., 2016) rather than potential species-specific fractionation (Sutton et al., 2013).

Thus, the combination of both $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ compositions in the water column and late Quaternary sediments off the coast of Peru has been applied as a measure to disentangle modern and past nutrient utilization and denitrification processes (Ehlert et al., 2015; Grasse et al., 2016). Comparison of modern dissolved $\text{Si}(\text{OH})_4$ and NO_3^- distributions and their corresponding isotopic ratios has shown that $\text{Si}(\text{OH})_4$ and NO_3^- concentrations and their stable isotopic signatures are strongly correlated within the surface mixed layer at nearshore and offshore areas, indicating that the signal preserved in the sediments depends on the degree of utilization of both nutrients (Grasse et al., 2016). Similarly, an initial comparison for the past 600 years based on one sediment core indicated that both isotope compositions were largely influenced by nutrient utilization, suggesting that denitrification in the water column only had a significant influence since ~ 1850 CE (Ehlert et al., 2015), thus partly contradicting previous interpretations of N-loss having been the main driver of changes in past $\delta^{15}\text{N}_{\text{bulk}}$ records.

At present, the features of the Peruvian upwelling system vary significantly with the El Niño–Southern Oscillation (ENSO) on interannual timescales. During warm phases of ENSO (El Niño) a weakening of the trade winds over the equatorial Pacific and an eastward displacement of the West Pacific warm pool (Picaut et al., 1996) cause warmer sea surface temperature anomalies in the central and eastern Pacific Ocean. Off the coast of Peru this causes the mixed layer (and thermocline/nutricline) depth to increase, decreasing the nutrient content (NO_3^- and iron, Fe) of upwelled waters and leading to a decrease in phytoplankton (mainly diatoms) abundance and productivity (Barber and Chávez, 1983; Chavez, 1989; Espinoza-Morriberón et al., 2017; Sanchez et al., 2000). In contrast, the cold phases of ENSO (La Niña) are associated with a stronger Walker circulation (west–east or zonal) and upwelling-favorable winds off the coast of Peru, resulting in negative sea surface temperature (SST) anomalies (Morón, 2000), a thermocline shoaling and higher phytoplankton productivity (Espinoza-Morriberón et al., 2017). Similar conditions have been reported to alternate on the multicentennial timescales during Northern Hemisphere cold and warm periods. These so-called El Niño- and La Niña-like mean states reflect larger-

scale oceanographic and climatic changes (Fleury et al., 2015; Rein, 2004; Yan et al., 2011). Accordingly, the climate of the last 600 years can be divided into two climatic phases consisting of the Current Warm Period (CWP, since 1800 CE) and the Little Ice Age (LIA, ca. 1400 to 1800 CE). Off the coast of Peru, the CWP has been characterized by dry (arid) conditions, strong upwelling intensity, as well as high productivity and intense N-loss processes, reflecting overall dominant La Niña conditions (Fleury et al., 2015; Salvattecchi et al., 2014b; Sifeddine et al., 2008). In contrast, within the present day main upwelling area between 10 and 15° S, the LIA was characterized by lower productivity and low denitrification intensity for the present day main upwelling area between 10 and 15° S (Díaz-Ochoa et al., 2009; Salvattecchi et al., 2014b; Sifeddine et al., 2008). Previous paleo-reconstructions agreed that these conditions were induced by weakening of the Walker circulation and reduction of the South Pacific Subtropical High (SPSH), as well as by a southward shift of the mean position of the Intertropical Convergence Zone (ITCZ) and the associated precipitation belt (Fleury et al., 2015; Sachs et al., 2009; Salvattecchi et al., 2014b; Sifeddine et al., 2008). These changes resulted in reduced LIA surface productivity and more oxygenated subsurface waters off the coast of Peru, as reflected by lower sedimentary BSi and total organic carbon (TOC) concentrations (Ehlert et al., 2015; Gutiérrez et al., 2009; Salvattecchi et al., 2014a) and Si/Fe ratios (Fleury et al., 2015) and supported by a marked reduction in the sedimentary concentrations of redox sensitive trace metals such as molybdenum and rhenium (Salvattecchi et al., 2014b; Sifeddine et al., 2008). However, these conditions did not prevail continuously but instead short-term variations during both the LIA and the CWP are, for example, mirrored by changes in diatom abundances, productivity sensitive element ratios indicative of productivity changes (Br/Fe) and $\delta^{15}\text{N}_{\text{bulk}}$ values (Fleury et al., 2015). These proxy records indicate multidecadal shifts between arid and humid conditions during the CWP and during the LIA when pronounced short-term periods of arid conditions occurred in particular (Fleury et al., 2015). The well-studied biogeochemical evolution of the Peruvian shelf over the last 600 years and the significant differences in productivity and subsurface oxygenation between the CWP and the LIA form the basis for our study to gain new insights into the relationship between nutrient utilization and denitrification via $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ records.

Here, our goal is to verify whether the southward increase in $\delta^{15}\text{NO}_3^-$ due to denitrification observed in the present day has persisted during the marked changes in upwelling intensity during the LIA and CWP, and therefore under different ENSO conditions, based on comparison of $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures of four different sediment cores retrieved along the entire gradient of upwelling strength of the southern Peruvian shelf. More specifically, we aim to detect the extent of variability in $\delta^{15}\text{N}_{\text{bulk}}$ caused as a function of denitrification and nutrient utilization during specific time peri-

Figure 1. Subsurface (100 m) oxygen concentration and current directions in the eastern equatorial Pacific. Inset map shows locations of cores M77/2-024-3 TC, M77/2-005-3 TC, M77/2-003-2 TC (this study), M77/1-470, B0405-13 and B0405-6 (Ehlert et al., 2015; Gutiérrez et al., 2009) in more detail. The bathymetry is given for 0 to 1000 m water depth in 50 m increments.

ods (i.e., LIA and CWP). Therefore, we present three new records for $\delta^{30}\text{Si}_{\text{BSi}}$ and BSi concentrations from the Peruvian shelf between 11 and 15° S covering the last 600 years. These are compared to previously published $\delta^{15}\text{N}_{\text{bulk}}$ data obtained from the same cores (Fleury et al., 2015) and $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ records from a fourth core from 14° S (Fig. 1; Ehlert et al., 2015).

Regional setting

Along the Peruvian margin the main source for the high amounts of upwelled nutrients ($30\ \mu\text{mol L}^{-1}$ for both $\text{Si}(\text{OH})_4$ and NO_3^- ; Bruland et al., 2005) is the subsurface Peru-Chile Undercurrent (PCUC), which flows southward along the continental slope and outer shelf between 4 and 14° S at a depth between 50 and 150 m, before it detaches from the shelf south of 15° S (Brink et al., 1983; Chaigneau et al., 2013; Toggweiler et al., 1991). Eastward-flowing subsurface waters of the Equatorial Undercurrent (EUC) and the Southern Subsurface Counter Current (SSCC) (see Fig. 1) feed the PCUC. These subsurface currents deliver $\text{Si}(\text{OH})_4$ and NO_3^- with mean preformed source signatures for $\delta^{30}\text{Si}(\text{OH})_4$ of $1.5 \pm 0.2\ ‰$ (Beucher et al., 2011; Ehlert et al., 2012; Grasse et al., 2013) and $\delta^{15}\text{NO}_3^-$ of $7.1 \pm 0.3\ ‰$

(1 SD; Rafter et al., 2012; Rafter and Sigman, 2016) for the EUC. Within the SSCC preformed $\delta^{15}\text{NO}_3^-$ values of $5.5 \pm 0.3\text{‰}$ (Rafter et al., 2012) are about 1.6‰ lower than the EUC, resulting in an approximate average PCUC value of $\sim 6\text{‰}$ (Fig. 2a; Mollier-Vogel et al., 2012).

The dissolved $\delta^{15}\text{NO}_3^-$ of subsurface waters (50–150 m water depth) increases southward (Equator, EQ, to 17° S; Mollier-Vogel et al., 2012) as a consequence of water column denitrification, while the dissolved $\delta^{30}\text{Si}(\text{OH})_4$ signature remains close to the source value of 1.5‰ for the PCUC (Fig. 2a; Ehlert et al., 2012). This difference in the evolution of the isotopic signature from north to south is caused by the anoxic conditions off the coast of Peru only increasing the $\delta^{15}\text{NO}_3^-$ signatures via denitrification in the subsurface but not affecting the $\delta^{30}\text{Si}(\text{OH})_4$ signatures. Accordingly, at the northern shelf between 1° N and 10° S, where subsurface O_2 concentrations $[\text{O}_2]$ are $>20\ \mu\text{mol L}^{-1}$, N-loss is not observed and the $\delta^{15}\text{N}_{\text{bulk}}$ values in the sediments range between 4‰ and 5‰, close to the $\delta^{15}\text{NO}_3^-$ source value of 6‰, thus indicating a high degree of NO_3^- utilization (Fig. 2b; Mollier-Vogel et al., 2012). In contrast, the $\delta^{30}\text{Si}_{\text{BSi}}$ signatures north of 10° S are more variable, reflecting an overall lower degree of $\text{Si}(\text{OH})_4$ utilization (Doering et al., 2016; Ehlert et al., 2012). At the central Peruvian shelf (10–12° S), where subsurface $[\text{O}_2]$ is $<20\ \mu\text{mol L}^{-1}$ (Fig. 2a), the subsurface source value of $\delta^{15}\text{NO}_3^-$ increases to 8.6‰ due to denitrification (Mollier-Vogel et al., 2012). The $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ values both increase as a consequence of higher $\text{Si}(\text{OH})_4$ utilization but decrease in NO_3^- utilization compared to the northern part of the study area (Fig. 2b), which reflects the interplay between increased upwelling intensity, high nutrient resupply and higher consumption via diatom productivity. In the southernmost part of the shelf (13–16° S), the highest productivity and upwelling intensity prevail today, leading to a further increase in the subsurface $\delta^{15}\text{NO}_3^-$ signature of up to 12.5‰ at 15° S, whereas surface sediment mean $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ values further increase, reflecting moderate utilization of both $\text{Si}(\text{OH})_4$ and NO_3^- (Fig. 2a–b). The supply of dissolved $\text{Si}(\text{OH})_4$ strongly increases from the northern shelf to the southern shelf area (Fig. 2c), reflecting the strength of the upwelling conditions. This increase in upwelling and productivity between 10 and 15° S results in high accumulation rates of BSi ($0.4\text{--}0.6\ \text{g cm}^{-2}\ \text{yr}^{-1}$; Ehlert et al., 2012) and total nitrogen (TN, $0.026\text{--}0.035\ \text{g cm}^{-2}\ \text{yr}^{-1}$; Mollier-Vogel et al., 2012) in the sediment (based on accumulation rates of Gutierréz et al., 2009). However, the NO_3^- supply, as indicated by subsurface (50–150 m) NO_3^- concentrations in the water column, slightly decreases from north to south, reflecting the loss of NO_3^- via denitrification.

2 Sample locations, methods and calculations

2.1 Core locations and age models

The new data in this study were obtained from three short, fine-laminated trigger cores retrieved from the main upwelling region off the Peruvian margin during the German R/V Meteor cruise M77/2 in 2008 as part of the Collaborative Research Center (SFB) 754 (Fig. 1). New records of $\delta^{30}\text{Si}_{\text{BSi}}$ and BSi concentrations were generated for cores M77/2-024-5TC (024-5TC; 11°05' S, 78°00' W, 210 m water depth), M77/2-005-3TC (005-3TC; 12°05' S, 77°40' W, 214 m water depth) and core M77/2-003-2TC (003-2TC; 15°06' S, 75°41' W, 271 m water depth). Single centimeter slices of the sediment cores were sampled for BSi and Si isotope measurements to ensure the availability of sufficient amounts of diatoms for silicon isotope analysis (Table 1). For core 003-2TC, additional BSi concentration measurements of material extracted from individual laminations was possible (Fleury et al., 2015). As previously published $\delta^{15}\text{N}_{\text{bulk}}$ values are based on samples from single laminations, these were averaged to 1 cm resolution when directly compared to the $\delta^{30}\text{Si}$ data in the following. Core locations are shown in Fig. 1. The age models were published before in Fleury et al. (2015). The age models for all cores are given in years CE.

2.2 Biogenic opal and silicon isotope analyses

The amount of BSi in the sediments was measured following an automated leaching method using sodium hydroxide (DeMaster, 1981; Müller and Schneider, 1993) with a precision of 1‰–2‰ (1 SD). Unfortunately, no material was left of the cores studied here to estimate dry bulk densities to calculate mass accumulation rates (MARs). Therefore, MAR values were used from nearby cores BO413 (12° S) and BO406 (14° S; Gutierréz et al., 2009), which were generally close to $0.02\ (\text{g cm}^{-2}\ \text{yr}^{-1})$ during the LIA and $0.03\ \text{g cm}^{-2}\ \text{yr}^{-1}$ during the CWP. The exact bulk MAR values ($\text{g cm}^{-2}\ \text{yr}^{-1}$) for each time period were multiplied by the fractional concentration of BSi and TN (Fleury et al., 2015) to calculate the MAR BSi and MAR TN (Figs. 2c and 6).

For the Si isotope measurements diatoms were extracted from the sediment by chemical and physical cleaning (11 and 32 μm sieve; heavy liquid separation with a sodium polytungstate solution set at $2.15\ \text{g mL}^{-1}$), as described in detail in Ehlert et al. (2012, 2013) and Doering et al. (2016). For all samples, the purity of the small diatom fraction (11–32 μm) was evaluated via light microscopy prior to dissolution and only pure ($>95\%$) diatom samples were treated further. All samples were dissolved in 1 mL 0.1 M NaOH and treated with 200 μL concentrated H_2O_2 (Suprapur). Sample solutions were diluted with 4 mL MQ water and neutralized with 0.1 mL 1 M HCl (Reynolds et al., 2008), followed by a chromatographic purification using 1 mL pre-

Figure 2. Latitudinal overview of present day (a) mean $\delta^{15}\text{N}_{\text{bulk}}$ (‰, black diamonds, 2 SD error bars) and $\delta^{30}\text{Si}_{\text{BSi}}$ (‰, white circles, 2 SD error bars), the dashed black line indicates the subsurface $\delta^{30}\text{Si}(\text{OH})_4$ source value of 1.5‰, the green solid line marks the $\delta^{15}\text{NO}_3^-$ source value, increasing southwards from 6‰ (0–8° S), to about 8‰ (10–12° S) and 12.5‰ (15° S). The red bar indicates the area of suboxic conditions in subsurface waters. The black rectangle marks the study area for downcore reconstruction (see also Fig. 1). (b) Nutrient utilization for NO_3^- (%), dark grey area) and $\text{Si}(\text{OH})_4$ (%), dashed area). (c) MAR TN ($\text{g cm}^{-2} \text{ yr}^{-1}$), MAR BSi ($\text{g cm}^{-2} \text{ yr}^{-1}$; for calculation see Sect. 2.6) and the nutrient supply (modified following Mollier-Vogel et al., 2012 and Ehlert et al., 2012).

cleaned AG50W-X8 cation exchange resin (BioRad, mesh 200–400) (de Souza et al., 2012). The Si isotopic compositions were determined in 0.6 ppm sample solutions on a NuPlasma HR MC-ICPMS at GEOMAR applying a standard-sample bracketing method (Albarède et al., 2004). Silicon isotopic compositions are reported in the δ -notation relative to the reference standard NBS28 in parts per thousand: $\delta^{30}\text{Si} = ((R_{\text{sample}}/R_{\text{standard}}) - 1) \cdot 1000$, where R_{sample} is the $^{30}\text{Si}/^{28}\text{Si}$ ratio of the sample and R_{standard} is the $^{30}\text{Si}/^{28}\text{Si}$ ratio of the NBS28. All $\delta^{30}\text{Si}$ measurements were run at least in triplicate, with uncertainties ranging between 0.05‰ and 0.27‰ (2 SD). Repeated measurements of an in-house diatom matrix standard gave average $\delta^{30}\text{Si}$ values of 1.03 ± 0.21 ‰ (2 SD $n = 15$). Long-term repeated measurements of the reference materials NBS28, IRMM018 and Big Batch gave average $\delta^{30}\text{Si}$ values of 0.00 ± 0.24 ‰ (2 SD), -1.40 ± 0.21 ‰ (2 SD, $n = 15$) and -10.60 ± 0.24 ‰ (2 SD, $n = 15$), respectively, in good agreement with literature values (Reynolds et al., 2007).

2.3 Diatom assemblage data

Diatom analysis of cores M77/2-024-5TC, 005-3TC and 003-2TC were published previously based on three slides per sample and counting of a minimum of 300 valves for

each sample (for details see Fleury et al., 2015). The diatom abundances are presented here for three groups representing different environmental conditions (Fig. 4e–g): upwelling species – *Chaetoceros* sp., *Skeletonema costatum*, *Thalassionema nitzschioides* var. *nitzschioides*; coastal planktonic species – *Actinocyclus* spp., *Atinoptychus* spp., *Asteromphalus* spp., and *Coscinodiscus* sp.; and other diatom species – *Nitzschia* spp., *Rhizosolenia* spp. and *Thalassiosira* spp., *Cyclotella* spp., and *Cocconeis* sp.;

The diatom assemblage abundance is compared to $\delta^{30}\text{Si}_{\text{BSi}}$ compositions for cores M77/2-024-5TC, 005-4TC and 003-2TC to investigate if changes in the assemblage have influenced the isotopic record. While diatom counts have been performed on bulk sediment samples $\delta^{30}\text{Si}_{\text{BSi}}$ was measured on the 11–32 μm size fraction. However, it was shown previously that this size range closely resembles the main assemblage, which allows for studying the influence of changes in the diatom assemblage on the $\delta^{30}\text{Si}_{\text{BSi}}$ record (Ehlert et al., 2012, 2013).

2.4 Nutrient utilization

The degree of nutrient utilization can be described assuming either Rayleigh-type (single input followed by no additional nutrients newly supplied to a particular parcel of water fol-

Table 1. Downcore record of core M77/2-024-5TC, M77/2-005-3TC and M77/2-003-2TC for $\delta^{30}\text{Si}_{\text{BSi}}$ (‰) and BSi content (wt %). The 2 SD represents the external reproducibility of repeated sample measurements.

Core	Age yr BP	Depth (mm)	BSi (wt %)	$\delta^{30}\text{Si}_{\text{BSi}}$ (‰)	2 SD

lowed by fractional loss as a function of production and export) or steady-state (continuous supply and partial consumption of nutrients causing a dynamic equilibrium of the dissolved nutrient concentration and the product) fractionation behavior (Mariotti et al., 1981). For simplification purposes we will only provide the values derived from steady-state fractionation, which was shown to better reflect upwelling conditions off the coast of Peru (Ehlert et al., 2012).

$$\% \text{Si(OH)}_4_{\text{consumed}} = 1 - \left(\left(\delta^{30}\text{Si} - \delta^{30}\text{Si(OH)}_4_{\text{source}} \right) / \varepsilon^{30} \right) \cdot 100$$

$$\% \text{NO}_3^-_{\text{consumed}} = [1 - (\delta^{15}\text{N} - \delta^{15}\text{NO}_3^-) / \varepsilon^{15}] \cdot 100, \quad (1)$$

with $\% \text{Si(OH)}_4_{\text{consumed}}$ or $\% \text{NO}_3^-_{\text{consumed}}$ being the percentages of the supplied Si(OH)_4 and NO_3^- that have been utilized. For this calculation we apply enrichment factors of -1.1‰ $^{30}\varepsilon$ ($\delta^{30}\text{Si}$, (De La Rocha et al., 1997) and -5‰ $^{15}\varepsilon$ ($\delta^{15}\text{N}$) and assume a constant source water signature of 1.5‰ for $\delta^{30}\text{Si(OH)}_4_{\text{source}}$ (i.e., the mean $\delta^{30}\text{Si(OH)}_4$ of the PCUC). The nutrient utilization for surface sediments calculated here is identical to the original publications (Fig. 2b; Mollier-Vogel et al., 2012; Ehlert et al., 2012). To evaluate the impact of changes in $^{30}\varepsilon$ on the $\delta^{30}\text{Si}$ signatures the potential influence of species-specific fractionation was tested based on the impact of a -2.1‰ enrichment factors of *Chaetoceros brevis* (Sutton et al., 2013). However, the estimated impact on past $\delta^{30}\text{Si}_{\text{BSi}}$ records, due to a change in the amount of *Chaetoceros* sp. present in the sediment was less than 5 % for all cores (M77/2-024-5TC, 005-3TC and 003-2TC) and thus did not alter the assumed $^{30}\varepsilon$ of -1.1‰ substantially (based on calculations presented in Doering et al., 2016; not shown). The impact of denitrification on the $\delta^{15}\text{NO}_3^-$ signatures of the past is assessed in the following section before calculating past NO_3^- utilization for the respective latitudes.

2.5 Calculation of the $\delta^{15}\text{NO}_3^-$ source signatures

Based on modern observations from the water column it is known that NO_3^- and Si(OH)_4 are incorporated in a 1 : 1 ratio when diatoms dominate the phytoplankton assemblage (Brzezinski, 1985; Ragueneau et al., 2000). The ratio of nutrients in the water column can, however, vary between 2 : 1 and 1 : 2 on the shallow Peruvian shelf (Grasse et al., 2016). Assuming a strict 1 : 1 uptake ratio of nutrients, the respective $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{Bulk}}$ values in the underlying sediments should also reflect a 1 : 1 ratio (indicated by white star “1” in Fig. 3a). Based on the known $\delta^{30}\text{Si(OH)}_4$ and NO_3^- source signatures of modern subsurface waters, we can calculate the actual nutrient utilization (see Sect. 2.4) and estimate the uptake ratio for NO_3^- : Si(OH)_4 (Fig. 3b). However, it is not possible to observe a significant correlation for the entire shelf area, given that there are only a few data points for the areas along the shelf (Figs. 2, 5a). We calculate past nutrient utilization and estimate the influence of denitrification on the $\delta^{15}\text{N}_{\text{bulk}}$ values based on the fact that on the shelf $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ values generally follow a positive linear regression (Figs. 3b, 5a). In order to estimate past changes in the $\delta^{15}\text{NO}_3^-$ source values, the $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ values were separately plotted against each other for the time periods of the CWP, the arid LIA and the humid LIA (Fig. 5b–d). Accordingly, the $\delta^{15}\text{NO}_3^-$ source value for each period was calculated based on the linear function assuming that the source $\delta^{30}\text{Si(OH)}_4$ signature always remained stable at 1.5‰ over time:

$$\delta^{30}\text{Si(OH)}_4 = a \cdot \delta^{15}\text{NO}_3^- + b, \quad (2)$$

or

$$\delta^{15}\text{NO}_3^- = \left(\delta^{30}\text{Si}(\text{OH})_4 - b \right) / a, \quad (3)$$

with a indicating the slope of the line and b the intercept. For $\delta^{30}\text{Si}(\text{OH})_4$ we used the value of 0.4‰ representing near 0% utilization (= source water $\delta^{30}\text{Si}(\text{OH})_4$ of 1.5‰ of the PCUC – 1.1‰ fractionation during uptake) to estimate the $\delta^{15}\text{NO}_3^-$ source. Accordingly, the values estimated by Eq. (3) represent the $\delta^{15}\text{NO}_3^-$ source value also assuming near 0% utilization of NO_3^- .

We calculated the linear regression based on all samples of the different cores from the different latitudes (11, 12, 14 and 15° S) during the CWP and the LIA. We also further differentiated between short-term productive phases (arid phases) and the generally prevailing humid El Niño-like conditions during the LIA (grey shadings in Fig. 4) and resolved the resulting equation based on Eq. (2) to estimate $\delta^{15}\text{NO}_3^-$. Only for the LIA (humid) phases was it not possible to directly calculate $\delta^{15}\text{NO}_3^-$ values based on the linear function from Eq. (2), due to near horizontal alignment of the $\delta^{15}\text{N}_{\text{bulk}}$ versus $\delta^{30}\text{Si}_{\text{BSi}}$ values (Fig. 5b). Therefore, for this time period the highest $\delta^{15}\text{N}_{\text{bulk}}$ value for each latitude was assumed to reflect ~ 100% utilization and was thus used as $\delta^{15}\text{NO}_3^-$ source value. This assumption might slightly overestimate the maximum utilization, which is only ~ 80% today (Fig. 2b), and therefore might underestimate the source value slightly. For all time periods and latitudes, the linear regressions as well as correlation coefficient (r^2) are given in the Supplement (Fig. S1). The results are presented in the following as the resulting $\delta^{15}\text{NO}_3^-$ source values and the theoretical ratio of nutrient utilization (i.e., 1 : 1 or 2 : 1, 15 : 1, etc.; Fig. 5b–d) for each latitudinal range to compare the latitudinal trends between the CWP and the LIA.

2.6 Calculation of nutrient supply

Based on these calculated subsurface $\delta^{15}\text{NO}_3^-$ values, we further calculated the change in nutrient utilization as well as nutrient supply for the different latitudes. Past nutrient utilization was calculated following Eq. (1). Given the estimate of nutrient demand and export productivity it is further possible to estimate changes in the supply with the relationship $\Delta\text{supply} = \Delta\text{demand} / \Delta\text{utilization}$ by applying the equation of Horn et al. (2011) given by

$$\text{Nutrient supply} = \frac{F_{\text{BSi/TN}}^{\text{sample}} F_{\text{BSi/TN}}^{\text{present}}}{\% \text{nutrient}_{\text{consumed}}^{\text{sample}} / \% \text{nutrient}_{\text{consumed}}^{\text{present}}}, \quad (4)$$

$F_{\text{opal/TN}}$ is the flux of BSi or TN and $\% \text{nutrient}_{\text{consumed}}$ is the percent of the $\text{Si}(\text{OH})_4$ or NO_3^- supply consumed (i.e., nutrient utilization). Given that there are no accumulation rates available for either the surface sediment samples or for any of the cores studied here to directly determine the export productivity directly, we used the BSi and TN values previously published (surface sediments; Mollier-Vogel

et al., 2012; Ehlert et al., 2012) and the new BSi values presented in this study, together with mass accumulation rates ($\text{g cm}^{-2} \text{yr}^{-1}$) for cores BO406-13 and 406-5 from Gutiérrez et al., 2009, to calculate the accumulation rates of BSi and TN (MAR; $\text{g cm}^{-2} \text{yr}^{-1}$). For the different time periods mean values for MAR BSi and MAR TN were calculated and the respective nutrient supply was calculated based on Eq. (4), indicating changes in the nutrient supply compared to modern values.

3 Results

3.1 Biogenic opal and silicon isotope signatures

The data of the sediment cores from the shelf area between 12 and 15° S presented here show an increase in BSi content from mean values of 13%–23% during the LIA to values of 21%–29% during the CWP. The $\delta^{30}\text{Si}$ records follow a similar trend of lower mean $\delta^{30}\text{Si}_{\text{BSi}}$ values of 0.8 ± 0.2 ‰ (2 SD, 12° S), 0.8 ± 0.1 ‰ (14° S) and 1 ± 0.2 ‰ (15° S) during the LIA to more variable and higher mean values of 1.3 ± 0.4 ‰ (12° S), 0.8 ± 0.4 ‰ (14° S) and 1.5 ± 0.2 ‰ (15° S) during the CWP (Fig. 3a–d; Table 1).

The diatom assemblages (Fig. 4e–g; based on Fleury et al., 2015) show an association of the amount of upwelling species and $\delta^{30}\text{Si}_{\text{BSi}}$ signatures, with decreases of up to 20% in upwelling species often accompanied by a reduction of $\delta^{30}\text{Si}_{\text{BSi}}$ by about 0.5‰–1‰. However, not every decrease in $\delta^{30}\text{Si}_{\text{BSi}}$ is mirrored by a change in the diatom assemblage and vice versa (e.g., Fig. 4f at 1650 CE). Overall, the diatom assemblage data indicate little change in the mean conditions and a slight reduction of upwelling strength at 12 and 15° S during the LIA in comparison to the CWP (Fig. 6). The most distinct shift of lower abundances of upwelling species (~ 50%) to higher values during the CWP (~ 70%) is found at 15° S (003-2TC) corresponding to the strongest changes in BSi and $\delta^{30}\text{Si}_{\text{BSi}}$ at this location.

The sedimentary BSi concentrations and $\delta^{30}\text{Si}_{\text{BSi}}$ signatures at 12° S (005-3TC) and 15° S (003-2TC) were lowest during the LIA (Fig. 4c, e), in agreement with previously published records from 11° S (M77/1-470; Fig. 4a) and 14° S (Ehlert et al., 2015; Fig. 4d). An exception is core 024-5TC (Fig. 4a) from 11° S, where $\delta^{30}\text{Si}$ mean values of the LIA (1.3 ± 0.4 ‰) are similar to CWP mean values (1.4 ± 0.1 ‰). Furthermore, both the BSi concentrations and $\delta^{30}\text{Si}_{\text{BSi}}$ signatures of core 024-5TC were significantly higher during the LIA than at nearby core M77/1-470 (Fig. 4a; Ehlert et al., 2015). However, comparison with the cumulative diatom assemblage indicates overall little difference in the amount of upwelling and coastal planktonic diatom species between the LIA and the CWP at 11° S (Fig. 4f), with intervals of reduced abundances of upwelling species generally lasting less than 50 years, much shorter than the 100 to 150 years intervals observed at 12 and 15° S. Furthermore, the finely

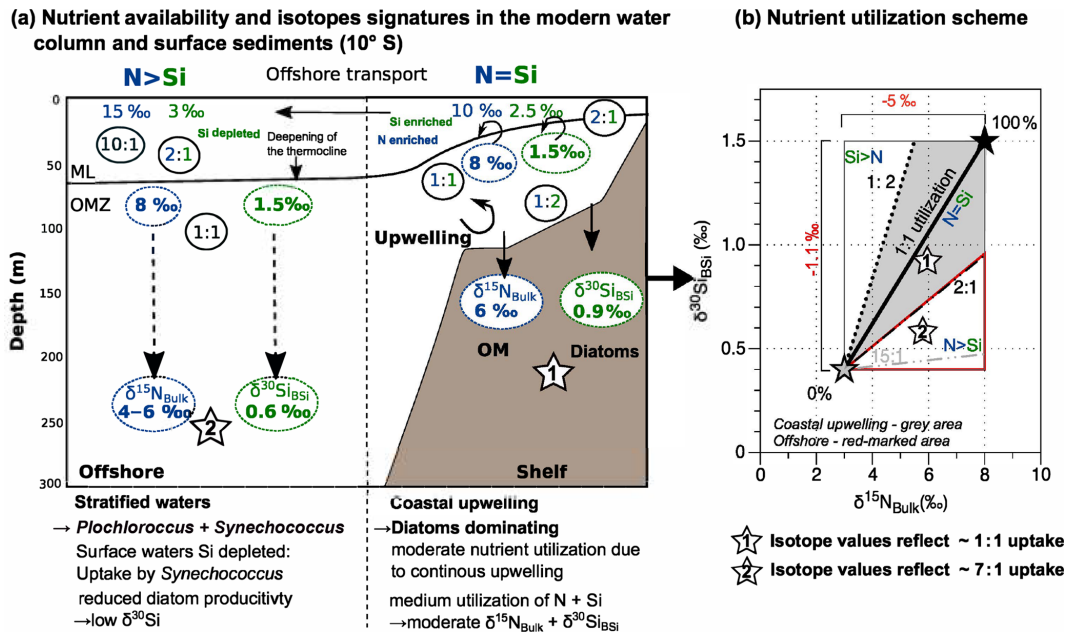

Figure 3. (a) Simplified schematic figure of the 10° S transect off the coast of Peru indicating the concentrations of $\text{Si}(\text{OH})_4$ (green) and NO_3^- (blue; given as enriched or depleted) together with the $\text{NO}_3^- : \text{Si}(\text{OH})_4$ ratios (N : Si). The stable isotope composition in the water column given as $\delta^{30}\text{Si}(\text{OH})_4$ and $\delta^{15}\text{NO}_3^-$ and the $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{Bulk}}$ signatures in underlying sediments. Diatoms are dominant on the shelf, whereas non-siliceous organisms (*Synechococcus*, *Prochlorococcus*) dominate the offshore productivity (modified from Grasse et al., 2016). (b) Schematic overview of nutrient utilization: the black star marks the source signature (or 100 % utilization) for $\delta^{15}\text{NO}_3^-$ (8‰) and for $\delta^{30}\text{Si}(\text{OH})_4$ (1.5‰) at the location, the grey star marks the theoretical isotopic compositions for ~ 0 % utilization, and the thick black solid line indicates the 1 : 1 utilization for N=Si. The $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{Bulk}}$ signatures from the shelf (white star 1) reflect an N:S uptake close to 1:1 while offshore signatures (white star 2) indicate higher N over Si utilization (N > Si). The rectangle indicates the total range of possible isotopic values. The respective fractionation factors are given in red.

laminated sediment layers do indicate short periods of higher productivity during the LIA in a phase with more arid conditions (Fig. 4, grey shading; for details see Fleury et al., 2015). Accordingly, the high mean BSi and $\delta^{30}\text{Si}_{\text{BSi}}$ values obtained from core 024-5TC may be an artifact of low sampling resolution with only two $\delta^{30}\text{Si}_{\text{BSi}}$ samples representing the time period between 1700 and 1800 CE and $\delta^{30}\text{Si}_{\text{BSi}}$ analyses not evenly covering all the short events (~ 50 years) of reductions in the abundance of upwelling diatom species (Fig. 4f). Alternatively, the increase in $\text{Si}(\text{OH})_4$ utilization, decoupled from an increase in diatom abundance (Fleury et al., 2015; not shown here) may indicate stronger silicification of the diatom frustules, as often observed under Fe-deficient conditions and associated with an increase in the $\text{Si}(\text{OH})_4 : \text{NO}_3^-$ incorporated by the diatoms (De La Rocha et al., 2000; Takeda, 1998; Wilken et al., 2011).

As previously shown, the $\delta^{15}\text{N}_{\text{bulk}}$ values of the three cores (M77/2-024-5TC, 005-3TC and 003-2TC) presented in this study were on average 0.8‰ lower during the LIA than during the CWP (Fleury et al., 2015). The $\delta^{15}\text{N}_{\text{bulk}}$ values reported for core 005-3TC (12° S) are close to values of nearby core B0406-13 (Gutiérrez et al., 2009). Similarly, the $\delta^{15}\text{N}_{\text{bulk}}$ values of core 003-2TC (15° S) agree well with pre-

viously published $\delta^{15}\text{N}_{\text{bulk}}$ record of core B0405-6 (14° S, Fig. 4j, k; Gutiérrez et al., 2009).

3.2 $\delta^{15}\text{NO}_3^-$ source signatures, nutrient utilization and supply

During the humid phases of the LIA the calculated $\delta^{15}\text{NO}_3^-$ source values were lower, reaching values of 6‰ between 11 and 12° S and 7.5‰ between 14 and 15° S (Figs. 5b, 6a). The calculated NO_3^- utilization was higher during this time, reaching values between 70 % and 90 %, while $\text{Si}(\text{OH})_4$ utilization ranged between 6 % and 60 %. The MAR TN was lowest (< 0.02 g cm⁻² yr⁻¹) during the LIA, however, with little difference between humid and arid phases (Fig. 6a, c, right side). The MAR BSi values were similar to today during the LIA (humid) ranging between 0.2 and 0.5 g cm⁻² yr⁻¹ (Figs. 2, 6a right side). The calculated NO_3^- supply was lowest during the LIA (humid) ranging between 0.3 and 0.7, with little change over latitude in accordance with the prevalence of more oxygenated waters, whereas the $\text{Si}(\text{OH})_4$ supply strongly increased from 0.5 to 3.8 at 12° S (Fig. 6a).

During the CWP the calculated $\delta^{15}\text{NO}_3^-$ source signatures based on Eqs. (2) and (3) result in values of 7.6‰ at 11° S, 8.6‰ at 12° S and 10.4‰ between 14 and 15° S during the

Figure 4. Downcore records of BSi (wt %) and $\delta^{30}\text{Si}_{\text{BSi}}$ (‰, 2 SD error bar of repeated sample measurements) records of cores: (a) M77/2-024-5TC and M77/1-470 (Ehlert et al., 2015), (b) M77/2-005-3TC (c), BO405-6 (Ehlert et al., 2015; Gutiérrez et al., 2009), and (d) M77/2-003-2TC. The cumulative diatom assemblages are compared to $\delta^{30}\text{Si}$ for core (e) M77/2-024-5TC, (f) M77/2-005-3TC and (g) M77/2-003-2TC. Upwelling species – light gray; coastal planktonic species – gray; other species – white; *Chaetoceros* sp. – dashed red line; $\delta^{30}\text{Si}_{\text{BSi}}$ – black dots. The black line indicates the transition between the LIA and the CWP. For comparison, previously published $\delta^{15}\text{N}_{\text{bulk}}$ (‰) are shown for cores (h) M77/2-024-5TC (Fleury et al., 2015), (i) M77/2-005-3TC (Fleury et al., 2015) and BO405-13 (Gutiérrez et al., 2009), (j) BO405-6 (Gutiérrez et al., 2009), and (k) M77/2-003-2TC (Fleury et al., 2015). All records are sorted by latitude from top (11° S) to bottom (15° S). The time intervals for the CWP (red) and the LIA (blue) are highlighted in (a); the horizontal grey shading indicates humid periods (Fleury et al., 2015).

CWP (Figs. 5c, 6b, S1 in the Supplement (Please confirm.)), which reflects a southward increase in $\delta^{15}\text{NO}_3^-$ source signatures as observed today (Fig. 2a). Based on these $\delta^{15}\text{NO}_3^-$ values the nutrient utilizations estimated based on Eq. (1) range between 30 % and 90 % for NO_3^- and 40 %–100 % for $\text{Si}(\text{OH})_4$ (Fig. 6b). During the LIA (arid) similar values are calculated with a $\delta^{15}\text{NO}_3^-$ mean value of 8 ‰ between 11 and 12° S, increasing to a value of 9 ‰ between 14 and 15° S (Fig. 6c). The respective nutrient utilization ranges between 2 % to 70 % for NO_3^- and 20 % to 85 % for $\text{Si}(\text{OH})_4$. The MAR TN were lower during the CWP by about 0.02 ($\text{g cm}^{-2} \text{yr}^{-1}$) than today and MAR BSi values were generally higher by about 0.1–0.35 ($\text{g cm}^{-2} \text{yr}^{-1}$). The calculated

$\text{Si}(\text{OH})_4$ supply indicates a slight increase compared to today (as indicated by positive values) but has remained rather stable around 1 over all latitudes, while NO_3^- supply also indicates values of ~ 1 at 11 and 15° S but the supply increased to 2 at 12° S (Fig. 6b, right side). During the LIA (arid) MARs of TN and BSi were both lower in comparison to the CWP, ranging between 0.014 and 0.017 ($\text{g cm}^{-2} \text{yr}^{-1}$) and 0.25–0.7 ($\text{g cm}^{-2} \text{yr}^{-1}$), respectively. The $\text{Si}(\text{OH})_4$ supply was similarly stable, as observed during the CWP, but slightly higher ranging from 0.6 to 1.55, while the NO_3^- supply was lower and decreased from north to south from 1 to 0.3.

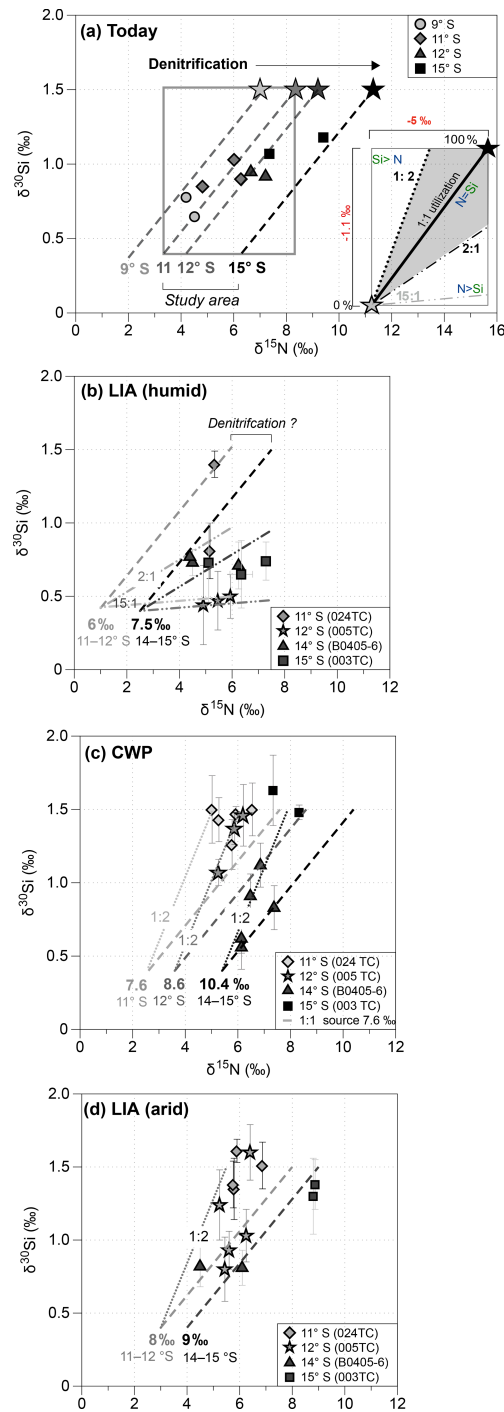

Figure 5. (a) Direct comparison of $\delta^{15}\text{N}_{\text{bulk}}$ versus $\delta^{30}\text{Si}_{\text{BSi}}$ for modern surface sediments (modified from Ehlert et al., 2015): the dashed lines indicate 1 : 1 utilization of different $\delta^{15}\text{N}_{\text{NO}_3^-}$ source values (7‰, 7.9‰, 8.35‰ and 11.3‰) between 9 and 15° S (based on Mollier-Vogel et al., 2012); the rectangle marks the respective range of isotope values that can be expected in sediment samples for nutrient utilization with source values of 1.5‰ ($\delta^{30}\text{Si}(\text{OH})_4$) and 8.35‰ ($\delta^{15}\text{N}_{\text{NO}_3^-}$). (inset of a) Schematic overview of nutrient utilization associated with changes in the isotopic compositions of both $\delta^{15}\text{N}$ and $\delta^{30}\text{Si}$: the black star marks the source signature (or 100 % utilization) for $\delta^{15}\text{N}$ and for $\delta^{30}\text{Si}$, the grey star marks the respective isotopic compositions for 0 % utilization, and the dashed black line indicates the 1 : 1 utilization for NO_3^- : $\text{Si}(\text{OH})_4$. Ratios that plot above the utilization lines reflect $\text{Si}(\text{OH})_4$ limitation, as indicated by the dotted dark grey and dotted light grey lines, representing ratios of 1 : 2, whereas data points below record stronger NO_3^- limitation, as indicated by the dashed dark grey and light grey lines representing ratios of 2 : 1 and 15 : 1. The rectangle indicates the total range of possible isotopic values. (b–d) Downcore comparison of $\delta^{15}\text{N}_{\text{bulk}}$ and $\delta^{30}\text{Si}_{\text{BSi}}$ for cores 024TC (diamonds), 005TC (grey stars), 003TC (grey squares) and BO405-6 (grey triangles; Ehlert et al., 2015) for the CWP and the LIA. For the LIA the sample values are separated into arid (d) and humid periods (b).

Figure 6. Latitudinal comparison of (from left to right) mean $\delta^{15}\text{N}_{\text{bulk}}$ (‰, black diamonds) and $\delta^{30}\text{Si}_{\text{BSi}}$ (‰, white circles) and the calculated $\delta^{15}\text{NO}_3^-$ source values (green line); the mean cumulative diatom abundance (%; calculated from Fleury et al., 2015); the respective nutrient utilization of NO_3^- (grey, solid line) and $\text{Si}(\text{OH})_4$ (dashed area and line); and MAR TN ($\text{g cm}^{-2} \text{yr}^{-1}$) and MAR BSi ($\text{g cm}^{-2} \text{yr}^{-1}$), together with nutrient supply relative to today for (a) the humid phases of the LIA, (b) the CWP, and (c) the arid phases of the LIA. Please note that for $\delta^{15}\text{N}_{\text{bulk}}$ values the mean was calculated for all available values for each time period and not only for samples for which $\delta^{30}\text{Si}_{\text{BSi}}$ values are also available. Error bars mark the 1 SD of the mean values.

4 Discussion

The aim of this study is to reconstruct the extent of variability in $\delta^{15}\text{N}_{\text{bulk}}$ caused as a function of denitrification versus nutrient utilization during specific time periods, i.e., the CWP and recurring short-term arid and humid periods during the LIA. The combination of $\delta^{15}\text{N}_{\text{bulk}}$ and $\delta^{30}\text{Si}_{\text{BSi}}$ signatures enables us to calculate the $\delta^{15}\text{NO}_3^-$ source signatures during these time periods and enabled us to estimate the extent of NO_3^- utilization that additionally contributed to the $\delta^{15}\text{N}_{\text{bulk}}$ recorded in the sediments. These data are combined with the $\delta^{30}\text{Si}_{\text{BSi}}$ signatures, calculated $\text{Si}(\text{OH})_4$ utilization calculations and nutrient supply, which will be discussed in the fol-

lowing (1) in comparison to modern conditions and (2) in the context of consistency with ENSO variability observed off the coast Peru and the eastern equatorial Pacific (EEP) during the last 600 years. Due to similar conditions prevailing during the CWP and arid phases of the LIA we will discuss these time periods together in the following.

4.1 Disentangling nutrient supply, utilization and N-loss processes: changes in the source water nitrate isotopic composition

4.1.1 Humid conditions of the Little Ice Age

During the humid LIA the $\delta^{30}\text{Si}_{\text{BSi}}$ values remain remarkably stable, whereas $\delta^{15}\text{N}_{\text{bulk}}$ values show a wide range, potentially reflecting enhanced NO_3^- limitation prevailing during humid phases (Fig. 5b). Such a shift towards increasing $\delta^{15}\text{N}_{\text{bulk}}$ values with consistently low $\delta^{30}\text{Si}_{\text{BSi}}$ values is indicative of weaker denitrification due to the higher subsurface oxygenation (only suboxic and not anoxic conditions), in agreement with reconstructions of redox conditions (Salvatteci et al., 2014b; Sifeddine et al., 2008). This is in agreement with the lower $\delta^{15}\text{NO}_3^-$ source signatures (6‰–7.5‰) and a decrease in the abundance of upwelling-indicating diatom species and *Chaetoceros* sp. (Figs. 4e–f and 6a; data from Fleury et al., 2015). Furthermore, our results indicate much higher NO_3^- utilization over $\text{Si}(\text{OH})_4$ utilization with ratios of up to 15 : 1 (Figs. 5b, 7a). This is in agreement with phytoplankton assemblage analyses during El Niño events when productivity has been reported to be dominated by non-siliceous phytoplankton groups (Sanchez et al., 2000), which is also observed today further off the coast of Peru (Fig. 3a; Grasse et al., 2016). Accordingly, with the prevalence of non-siliceous phytoplankton groups, more NO_3^- than $\text{Si}(\text{OH})_4$ is utilized (Conley and Malone, 1992; Wilkerson and Dugdale, 1996) and the ratio might shift to ratios of up to 15 : 1 (Figs. 3b, 7a; Grasse et al., 2016). However, the conditions found offshore today are based on surface waters that originate from the shelf area where diatom blooms prevail, thus already being depleted in $\text{Si}(\text{OH})_4$ and might not provide an adequate analogue for the conditions prevailing during the humid LIA phases (Figs. 5b, 6a). The calculated NO_3^- supply was lowest with little change over latitude in accordance with prevalence of more oxygenated waters, whereas the $\text{Si}(\text{OH})_4$ supply strongly increased, especially at 12° S (Fig. 6a). However, the calculated increased $\text{Si}(\text{OH})_4$ supply likely reflects the change in nutrient uptake (i.e., nutrient ratio) due to stratification and potential Fe limitation rather than an actual increase in $\text{Si}(\text{OH})_4$ supply reaching surface waters. Accordingly, we observe a high $\text{Si}(\text{OH})_4$ supply but low utilization, reflecting a low $\text{Si}(\text{OH})_4$ demand at the time. The NO_3^- supply appears to be lower than today, but the strongly enhanced NO_3^- utilization indicates a higher NO_3^- demand. This shift towards a decreased $\text{Si}(\text{OH})_4$ but an increased NO_3^- demand further supports a change in the nutrient uptake ratio by phytoplankton ($\text{NO}_3^- : \text{Si}(\text{OH})_4 = 2 : 1$ or 15 : 1, Figs. 5b, 7a). Regarding the high Si supply, it is also possible that it was actually bound by non-siliceous phytoplankton species, such as *Synechococcus* and not by diatoms as observed further offshore today (Fig. 3a; Grasse et al., 2016). However, these species are more likely to be recycled within the water column and Si stored within their cells is thus remineralized and

not transported to the sediment. This might be the reason we observe low BSi (%) values and the $\delta^{30}\text{Si}_{\text{BSi}}$ remain equally low (Figs. 4, 5b).

4.1.2 The Current Warm Period and arid phases of the Little Ice Age

The calculated $\delta^{15}\text{NO}_3^-$ source values based on linear regression between $\delta^{15}\text{N}_{\text{bulk}}$ and $\delta^{30}\text{Si}_{\text{BSi}}$ indicate an increase in the $\delta^{15}\text{NO}_3^-$ source signatures of upwelled subsurface waters from north to south from ~7‰ to 10‰ during the CWP and arid phases of the LIA, similar to those observations for modern conditions (Figs. 2a, 5c–d, 7b). This is in agreement with high contributions of upwelling diatoms and *Chaetoceros* sp. during both time periods (Figs. 4e–g. and 6b–c; data from Fleury et al., 2015). The calculated $\text{Si}(\text{OH})_4$ and NO_3^- supplies indicate a slight increase compared to today with $\text{Si}(\text{OH})_4$ supply increasing and NO_3^- supply decreasing towards the southern shelf. The latter agrees with continuous denitrification in the southern area causing a loss of NO_3^- . Furthermore, nutrient utilization for both NO_3^- and $\text{Si}(\text{OH})_4$ were moderate to high (~30%–90%; Figs. 6b–c, 7b), similar to modern values between 10 and 15° S (Fig. 2b; Mollier-Vogel et al., 2012; Ehlert et al., 2012). Due to the incomplete utilization of NO_3^- , the increasing $\delta^{15}\text{NO}_3^-$ source values are also only partially reflected in the $\delta^{15}\text{N}_{\text{bulk}}$ signatures for the CWP and the LIA (arid) as previously reported for signatures from surface sediments (Mollier-Vogel et al., 2012). Especially during the CWP, we calculate about 20%–40% lower NO_3^- utilization compared to today (Fig. 2b) but at the same time NO_3^- supply increased, while $\text{Si}(\text{OH})_4$ supply was only slightly higher compared to today and remained rather stable with latitude (Fig. 6b, right side). Apparently, the nutrient concentration of upwelled waters during the CWP has been different from today, which is also supported by a difference in the ratio of $\text{NO}_3^- : \text{Si}(\text{OH})_4$ utilization (Fig. 5c). Accordingly, unlike today's surface sediment data, the cores at 11S and 12° S show substantially higher $\delta^{30}\text{Si}_{\text{BSi}}$ values during both the CWP and the LIA (arid) (Fig. 5c–d). These higher $\delta^{30}\text{Si}_{\text{BSi}}$ signatures result in a $\text{NO}_3^- : \text{Si}(\text{OH})_4$ utilization that has shifted towards a 1 : 2 ratio, indicating enhanced utilization of $\text{Si}(\text{OH})_4$ over NO_3^- , potentially leading to $\text{Si}(\text{OH})_4$ limitation, in agreement with the lower $\text{Si}(\text{OH})_4$ supply in comparison to NO_3^- and higher $\text{Si}(\text{OH})_4$ than NO_3^- utilization rates (Fig. 6b–c). Such a decoupling of Si and N within diatoms can be caused by biogeochemical changes, such as Fe availability altering the Si : N uptake dynamics (Hutchins and Bruland, 1998; Takeda, 1998), whereby elevated Si : N ratios are characteristic for Fe-limited diatom communities (Takeda, 1998). Accordingly, increased uptake of Si over N can lead to a $\text{Si}(\text{OH})_4$ limitation, as found during the CWP and the LIA arid phases at 11 to 12° S (Figs. 5c–d, 6b–c, 7b). The reason may have been that less Fe was upwelled at the narrow shelf between 11 and 16° S, which led to Fe-

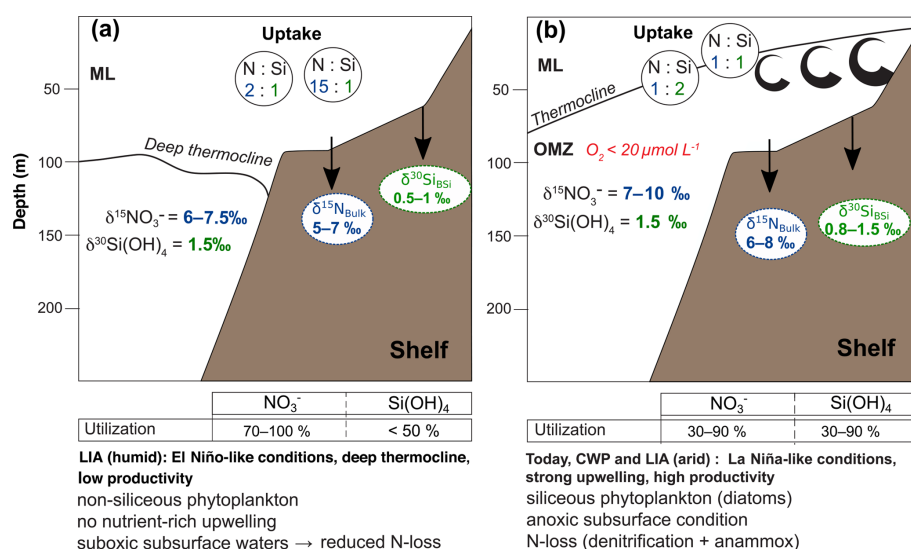

Figure 7. Schematic nutrient (Si(OH)_4 and NO_3^-) cycle models for the Peruvian mixed layer (ML) and oxygen minimum zone (OMZ) along the shelf area (0–200 m water depth) during the last 600 years. The NO_3^- : Si(OH)_4 (N : Si) indicates the ratio in which both nutrients are taken up during biological production in surface waters.

limitation during progressing diatom blooms (Doering et al., 2016).

4.2 The coupling between the biogeochemical cycle and ENSO variability

Recent evidence shows that a cool EEP plays a key role in climate change due to its linkage to a slowdown in global warming (England et al., 2014; Kosaka and Xie, 2013), highlighting the importance of understanding Pacific climate variability in the past (Rustic et al., 2015). The last millennium has been divided into warmer global conditions over the Medieval Warm Period (MWP), colder temperatures over the LIA and rising temperatures since the beginning of the CWP (Mann et al., 1999). The transition between the MWP and the LIA (~ 1150 to 1500 CE) has been associated with an anomalous strong zonal SST gradient and with transitional Northern Hemisphere (NH) cooling into the LIA, as evidenced by cooler SSTs at Galápagos (Rustic et al., 2015). After ~ 1500 CE, the EEP cooling trend ended and local SSTs began to increase until around 1600 CE, when an anomalous weak zonal gradient was established when the EEP temperatures reversed from cooling to warming. This reversal occurred when the NH descended into the coldest part of the LIA and persisted throughout most of the LIA resulting in an extended El Niño-like mean state (Mann et al., 2009). Evidence links the ITCZ to hemispheric warming and cooling cycles, implying southward ITCZ displacements during NH cold periods (Chiang and Bitz, 2005; Schneider et al., 2014). Accordingly, a southward shift of the ITCZ during the MWP-LIA transition has been proposed for the Atlantic and Pacific (Haug et al., 2001; Peterson and Haug, 2006; Sachs et

al., 2009). The El Niño-like conditions during the LIA have been associated to a gradual intensification of the fluvial input of sediments to the continental shelf, as reflected by an increase in the terrigenous sediment flux (Briceño-Zuluaga et al., 2016; Gutiérrez et al., 2009; Sifeddine et al., 2008) and changes in the radiogenic isotopic composition of the terrigenous fraction due to changes in the provenance and material transport (Ehlert et al., 2015), as well as better oxygenation and a lower productivity in the Peruvian upwelling area (Gutiérrez et al., 2009; Salvattecchi et al., 2014b; Sifeddine et al., 2008). Accordingly, most of the LIA, i.e., the humid phases, have been characterized by low productivity and weak denitrification intensity between 10 and 15° S (Díaz-Ochoa et al., 2009; Salvattecchi et al., 2014b; Sifeddine et al., 2008), which is supported by the absence of a significant southward increase in the source value of $\delta^{15}\text{NO}_3^-$ reconstructed from our records (Figs. 5b, 6a). Correspondingly, high $\delta^{15}\text{N}_{\text{bulk}}$ and little change in reconstructed NO_3^- supply indicate more complete NO_3^- utilization during the LIA (humid), while $\delta^{30}\text{Si}_{\text{BSi}}$ signatures and utilization remained low and Si supply high (Fig. 6a). This indicates a shift towards a dominance of non-siliceous phytoplankton productivity causing NO_3^- limitation and low uptake of Si. This is in agreement with modern conditions during El Niño events for which physical-biogeochemical models, together with in situ and satellite observations (1958–2008), have shown that the temperatures and sea level increase, the thermocline and nutricline deepens, and the phytoplankton (mainly diatoms) and nutrient concentration decrease along the Peruvian coast (Espinoza-Morriberón et al., 2017). Coastal trapped waves propagating along the coast can seasonally increase the depth of thermocline and nutricline, decreasing the NO_3^- vertical

flux into the surface layer. The NO_3^- and Fe content of the upwelling source waters may also strongly decline (Espinoza-Morriberón et al., 2017). Our calculations show that phases of lower productivity during so-called El Niño-like conditions during the LIA (humid) have a $\delta^{15}\text{NO}_3^-$ source delivered to the Peru upwelling area similar to today (Fig. 6a), but due to less or no denitrification $\delta^{15}\text{NO}_3^-$ source does not increase southward (Figs. 5b, 6a). Instead $\delta^{15}\text{N}_{\text{bulk}}$ values are mainly affected by the variability of NO_3^- concentrations, which seem to be the limiting factor for primary productivity (PP) similar to that observed during El Niño events today (Espinoza-Morriberón et al., 2017). The stronger stratification due to deepening of the nutricline potentially does not allow for similarly efficient N remineralization (or N is transported offshore due to eddy activity, Espinoza-Morriberón et al., 2017) and may result in NO_3^- to be utilized more strongly than $\text{Si}(\text{OH})_4$ (Fig. 7a). Accordingly, the NO_3^- supply was diminished while $\text{Si}(\text{OH})_4$ was still available.

Finely laminated sediment from the LIA from the oxygen minimum zones (OMZs), which have also been used in this study, resolve multidecadal variations in precipitation over the continent, and of variations in detrital and biogenic fluxes in relation to precipitation and upwelling intensity (Briceño-Zuluaga et al., 2016; Díaz-Ochoa et al., 2009; Fleury et al., 2015, 2016; Salvattecchi et al., 2014a). Stable oxygen isotope compositions of individual planktic foraminifera point to greater ENSO activity (high frequency between alternating La Niña and El Niño conditions) in the EEP based on records from the Galápagos (Rustic et al., 2015). It was shown by coupled models that such multi-decadal variation in ENSO amplitude can arise from episodic strengthening and weakening of the thermocline feedback (Borlace et al., 2013). The difference we observed in the isotopic evolution of nutrients ($\delta^{15}\text{N}$ and $\delta^{30}\text{Si}$) between the arid and humid phases during the LIA support the development of multidecadal phases of prevailing La Niña- or El Niño-like conditions. Similar interannual variance has been observed based on organic carbon and carbonate proxies during the LIA within the California current system, which the authors related to large ENSO events in contrast with an apparent reduction in such variability during the CWP (Abella-Gutiérrez and Herguera, 2016).

This El Niño-like mean state appears to have ended at the beginning of the CWP (Rustic et al., 2015). Evidence for increasing precipitation off the coast of Panama after 1700 CE likely reflects the northward shift of the ITCZ (Linsley et al., 1994) from its more southerly LIA position. During the CWP the OMZ intensified and marine productivity increased together with surface temperature cooling and an increase in terrigenous material input (Briceño-Zuluaga et al., 2016; Gutiérrez et al., 2011). We find that the CWP and the LIA (arid) are characterized by high upwelling intensity, productivity, and N-loss processes (Fleury et al., 2015; Salvattecchi et al., 2014b; Sifeddine et al., 2008) and are associated with southward increasing $\delta^{15}\text{NO}_3^-$ source signatures caused by denitrification, reflecting moderate NO_3^- utilization and

moderate to high $\text{Si}(\text{OH})_4$ utilization (Fig. 7b). The highest $\delta^{30}\text{Si}_{\text{BSi}}$ and utilization values at 15°S are potentially caused by progressive Fe limitation during diatom blooms, causing a $\text{NO}_3^- : \text{Si}(\text{OH})_4$ ratio of up to 1 : 2. Southward increasing $\delta^{15}\text{N}_{\text{bulk}}$ values and calculated $\delta^{15}\text{NO}_3^-$ demonstrate the consistent incorporation of higher isotopic compositions due to subsurface denitrification under anoxic subsurface conditions, in agreement with decreasing NO_3^- supply illustrating the N-loss process.

5 Conclusions

Based on a compilation of new and previously published $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ records of several short sediment cores from the southern Peruvian shelf ($11\text{--}15^\circ\text{S}$), we present a new evaluation of the impact of denitrification on the isotopic source signature of NO_3^- and its subsequent utilization. As denitrification increases southward along the shelf today, we applied a latitudinal comparison between $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures in modern surface and latest Holocene sediments. Given that during the last 600 years both proxies have mainly been influenced by nutrient utilization, we performed a novel calculation of subsurface $\delta^{15}\text{NO}_3^-$ based on the linear regression of $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures for the CWP and the LIA (arid versus humid conditions). Our results show that low productivity and higher subsurface oxygenation (suboxic conditions) during the humid phases of LIA were associated with low $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures. The latitudinal comparison of $\delta^{30}\text{Si}_{\text{BSi}}$ versus $\delta^{15}\text{N}_{\text{bulk}}$ signatures supports decreased influence of subsurface denitrification on the NO_3^- isotope distribution, with lower and more uniform $\delta^{15}\text{NO}_3^-$ source signatures between 6‰ and 7.5‰. However, NO_3^- utilization was significantly higher, while $\text{Si}(\text{OH})_4$ utilization was lower because the $\text{Si}(\text{OH})_4$ supply was higher compared to the demand. This change in nutrient utilization is reflected by a $\text{NO}_3^- : \text{Si}(\text{OH})_4$ uptake ratio of up to 15 : 1, suggesting a shift from a diatom-dominated regime to one dominated by non-siliceous phytoplankton. This agrees with El Niño-like conditions prevailing during most of the LIA, accompanied by a deepening of the thermocline and lower nutrient availability. During the CWP and the sporadic arid conditions during the LIA, the isotopic compositions of NO_3^- increased southward due to subsurface denitrification under strong oxygen depletion, similar to modern conditions. Furthermore, enhanced $\text{Si}(\text{OH})_4$ over NO_3^- uptake characterized nutrient utilization over NO_3^- uptake, reflecting strong diatom blooms, as can be observed, potentially leading to progressive Fe limitation increasing the Si : N uptake ratio of diatoms to 2 : 1.

In summary, our results constitute an improvement of the application of combined $\delta^{30}\text{Si}_{\text{BSi}}$ and $\delta^{15}\text{N}_{\text{bulk}}$ signatures as a powerful tool to differentiate between past changes in subsurface denitrification, nutrient utilization and supply but

also changes in the nutrient ratios as a result of either micro- (Fe) or macro-nutrient limitation.

Data availability. All data are available at <https://doi.pangaea.de/10.1594/PANGAEA.901858> (Doering et al., 2019).

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/bg-16-2163-2019-supplement>.

Author contributions. KD conducted the sampling of the sediment cores at Bordeaux University. KD prepared the samples and performed the isotope measurements. KD wrote the manuscript with contributions from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.
